STOCHASTIC BIFURCATION MODELS

Richard F. Bass and **Krzysztof Burdzy**

Abstract. We study an ordinary differential equation controlled by a stochastic process. We present results on existence and uniqueness of solutions, on associated local times (Trotter and Ray-Knight theorems), and on time and direction of bifurcation. A relationship with Lipschitz approximations to Brownian paths is also discussed.

Research partially supported by NSF grant DMS-9700721.

1. Introduction.

Let B_t be a continuous function of t, let $t_0, x_0, \beta_1, \beta_2 \in \mathbb{R}$, and consider the ordinary differential equation

$$\frac{dX_t}{dt} = \begin{cases} \beta_1 & \text{if } X_t < B_t, \\ \beta_2 & \text{if } X_t > B_t, \end{cases} \qquad t \in \mathbb{R}, \qquad X(t_0) = x_0. \tag{1.1}$$

Among the results we prove are the following:

(1) Although in general there will not be a unique solution to (1.1), there will be a unique Lipschitz solution to (1.1) if B_t is a typical Brownian motion path.

(2) Let B_t be a Brownian motion with $B_0 = 0$ and let $X_t^{x_0}$ denote the solution to (1.1) when $t_0 = 0$ and $X(t_0) = x_0$. The map $y \to X_t^y$ is a one-to-one map of $\mathbb{R}$ onto $\mathbb{R}$. The smoothness of this map is controlled by the local time at 0 of $X_t^y - B_t$. If we call this local time L_t^y and β_1, β_2 satisfy suitable assumptions, then L_t^y is jointly continuous in y and t and $\{L_\infty^y, y \geq 0\}$ and $\{L_\infty^{-y}, y \geq 0\}$ are strong Markov processes. We show that this implies that for a fixed $t > 0$, the function $y \to X_t^y$ is of class $C^{1+\gamma}$ with $\gamma < 1/2$, but it is not $C^{3/2}$.

(3) As we shall see below, (1.1) is an example of a bifurcation model; if B_t is a Brownian motion, $\beta_1 < 0$ and $\beta_2 > 0$, each of the events $\{\lim_{t\to\infty} X_t = +\infty\}$ and $\{\lim_{t\to\infty} X_t = -\infty\}$ has positive probability. The bifurcation time is defined by $= \sup\{t : X_t = B_t\}$. We calculate both the probability of $\{\lim_{t\to\infty} X_t = +\infty\}$ and the expectation of the bifurcation time using excursion theory.

(4) The equation (1.1) sheds light on the best Lipschitz approximation to Brownian paths. In particular we obtain an estimate on the lower bound on the best constant in the Komlós-Major-Tusnády result concerning strong approximations of Brownian motion by random walks.

Equation (1.1) is similar to an equation that arose in the course of an economic study and its accompanying probabilistic model in Burdzy, Frankel, and Pauzner (1997, 1998). These papers introduce and study an economics model whose technical side is based on the following equation:

$$\frac{dX_t}{dt} = \begin{cases} -\beta X_t & \text{if } X_t < f(B_t), \\ \beta(1 - X_t) & \text{if } X_t > f(B_t), \end{cases} \qquad t \geq 0, \qquad X(0) = x_0 \in (0,1), \tag{1.2}$$

where B_t is a Brownian motion starting from $B_0 = b_0$, $\beta > 0$ is a fixed constant, and f is a non-increasing Lipschitz function. The case when $x_0 = f(b_0)$ is of special interest. Results on the time and direction of the stochastic bifurcation were crucial elements of these two papers.

We also consider the following equation, more general than (1.1).

$$\frac{dX_t}{dt} = \begin{cases} \beta_1 |X_t - B_t|^{\alpha_1} & \text{if } X_t < B_t, \\ \beta_2 |X_t - B_t|^{\alpha_2} & \text{if } X_t > B_t, \end{cases} \qquad t \in \mathbb{R}, \qquad X(t_0) = x_0. \tag{1.3}$$

(If $\alpha_1 = \alpha_2 = 0$, then (1.3) reduces to (1.1).) Equation (1.3) was inspired by the following model. Consider a pendulum with rigid arm which is turned upside down (see Fig. 1.1).

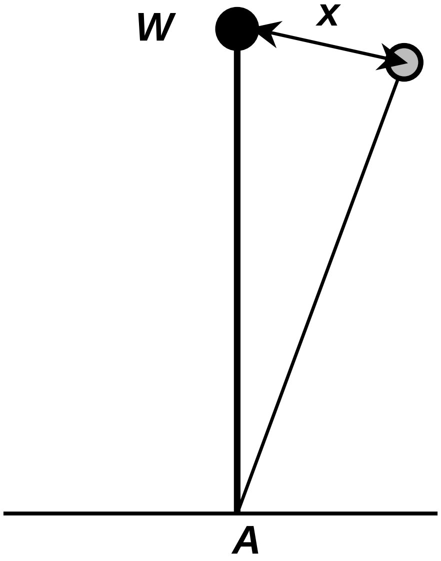

Figure 1.1.

Let X_t denote the distance of the weight W from its unstable rest position at the top of the vertical arm. When $X_t = x$ and x is small, the weight is about $c_1 x^2$ units below its rest position and, therefore $c_2 x^2$ units of potential energy must have been converted to kinetic energy, given by $c_3(dX/dt)^2$. Hence, we have the approximate relationship $dX/dt = c_4 X_t$, assuming infinitesimally small velocity at the rest position. Note that if the initial velocity at the rest position is close to zero, then the time it takes the pendulum to move any fixed non-zero distance from the rest position is very large. We now add stochastic oscillations to our pendulum model. We suppose that the base A of the pendulum vibrates according to a Brownian motion B_t. Then the position X_t of the weight W relative to A is $X_t - B_t$ and we have $dX/dt = c_4(X_t - B_t)$, which is (1.3) with $\alpha_1 = \alpha_2 = 1$ and $-\beta_1 = \beta_2 = c_4$.

The solutions to (1.1) exhibit fast switching between two kinds of excursions. See Karatzas and Shreve (1988, Sect. 6.5) for a closely related model. Mandelbaum, Shepp, and Vanderbei (1990) also consider a model with fast switching between two kinds of excursions, but we were not able to find a direct connection with our own model.

The rest of the paper consists of five sections. Section 2 contains results on existence and uniqueness of solutions to (1.1), (1.3), and related equations. The process B_t will generally be a Brownian motion, but Theorems 2.3 and 2.4 also apply to some fractional Brownian motions (see Examples 2.3 and 2.4).

Let X_t^y denote the solution to (1.1) with $X_0^y = y$. For a fixed $t \geq 0$, the function $y \to X_t^y$ is a transformation of $\mathbb{R}$ onto itself. How smooth is this map? How many derivatives does the function $y \to X_t^y$ have and are they continuous? To answer these questions, one is led to study the local time of $X_t^y - B_t$. Section 3 is devoted to a number of results about local times related to (1.1), including analogues of the Trotter and Ray-Knight theorems. See Knight (1981), Leuridan (1998), Norris, Rogers and Williams (1987), Revuz and Yor (1991) and Yor (1997) for old and new variants of the Ray-Knight theorem. Our local times are defined as local times at points, but they may also be viewed as local times of Brownian motion on a random curve—see (5.15) in Föllmer, Protter, and Shiryaev (1995) for a result on local times on non-random curves.

Section 4 gives explicit formulae for the probability of upward bifurcation for the equation (1.3) and the expected bifurcation time for (1.1), with some indication how to proceed in the more general case (1.3). This extends results from Burdzy, Frankel and Pauzner (1998). Section 5 takes a look at the solutions to (1.1) as Lipschitz approximations to the Brownian path. As a consequence we obtain some lower bounds related to the Komlós-Major-Tusnády construction; see Theorem 5.7. Finally, Section 6 is a list of open problems.

In Sections 3-5, we consider Brownian motion defined on the whole real line $\mathbb{R}$, i.e., the process $\{B_t, -\infty < t < \infty\}$, where $\{B_t, t \in (0,\infty)\}$ and $\{B_{-t}, t \in (0,\infty)\}$ are independent Brownian motions starting from 0 with variance $\mathbb{E}B_t^2 = \mathbb{E}B_{-t}^2 = \sigma^2 t$. Unless stated otherwise, we will assume that all Brownian motions (including those with drift and/or reflection) have infinitesimal variance σ^2, and that all constants are strictly positive and finite.

Section 3 of the paper was inspired by unpublished heuristic calculations involving local times which were a part of an earlier project of David Frankel, Ady Pauzner, and the second author. We would like to thank the many colleagues who kindly gave us advice

on various aspects of the model: Robert Adler, Ludwig Arnold, Jean Bertoin, Miklos Csörgö, Burgess Davis, Laurent Decreusefond, David Frankel, Mike Harrison, Haya Kaspi, Frank Knight, Jim Kuelbs, Avi Mandelbaum, Ady Pauzner, Jim Pitman, Philip Protter, Emmanuel Rio, Ruth Williams, Marc Yor, and Ofer Zeitouni.

2. Existence and uniqueness of solutions. In this section we present several theorems on the existence and uniqueness of solutions to differential equations similar to (1.1). There is considerable overlap among the theorems, but each contains cases not covered by the other. We first present our main results. They are followed by some remarks and examples. The proofs are relegated to the end of the section.

We start with the equation

$$\frac{dX}{dt} = \begin{cases} \beta_1 |X_t - B_t|^{\alpha_1} & \text{if } X_t < B_t, \\ \beta_2 |X_t - B_t|^{\alpha_2} & \text{if } X_t > B_t, \end{cases} \qquad t \in \mathbb{R}, \qquad X(t_0) = x_0. \tag{2.1}$$

where B_t is a Brownian motion, $\alpha_1, \alpha_2 > -1$, and $\beta_1, \beta_2 \in \mathbb{R}$.

First note that the function $X_t = B_t$ is a solution to (2.1) with $t_0 = 0$ and $x_0 = 0$, because neither of the conditions on the right hand side of (2.1) is ever satisfied. We would like to disregard such a solution for two reasons. First, the economics model behind (1.2) required that the solutions to (1.2) be Lipschitz. Second, the example $X_t = B_t$ is rather artificial. For $\alpha_1, \alpha_2 \geq 0$ it is natural to require that X_t is a Lipschitz function. We generalize this to all $\alpha_1, \alpha_2 > -1$ by writing an integrated version of (2.1), namely,

$$X_t = x_0 + \int_{t_0}^{t} \left[\beta_1 |X_s - B_s|^{\alpha_1} \mathbf{1}_{\{X_s - B_s \leq 0\}} + \beta_2 |X_s - B_s|^{\alpha_2} \mathbf{1}_{\{X_s - B_s > 0\}} \right] ds. \tag{2.2}$$

It is easy to see that solutions to (2.2) satisfy (2.1), but the example $X_t = B_t$ shows that the opposite statement is not true.

Theorem 2.1. *For fixed $t_0, x_0, \beta_1, \beta_2 \in \mathbb{R}$, $\sigma^2 > 0$, and $\alpha_1, \alpha_2 > -1$, there exist a Brownian motion B_t and a process X_t which satisfy (2.2) with the initial condition as in (2.1). The solution X_t is unique in law. We may construct X_t in such a way that (X_t, B_t) is a strong Markov process relative to the appropriate filtration. If we assume in addition that $\alpha_1, \alpha_2 \geq 0$, then for a given Brownian motion B_t there exists a unique solution to (2.2),* a.s.

Our next theorem is a result on existence. We will state the result for the following generalization of the equation (1.1),

$$\frac{dX_t}{dt} = \begin{cases} F_1(X_t) & \text{if } X_t > B_t, \\ F_2(X_t) & \text{if } X_t < B_t, \end{cases} \qquad t \in \mathbb{R}, \qquad X(t_0) = x_0. \tag{2.3}$$

Theorem 2.2. *Assume that F_1 and F_2 are continuous functions and that $|F_1|$ and $|F_2|$ are bounded by $\beta < \infty$. If B_t is a continuous process, then (2.3) has a Lipschitz solution, a.s. There exists a maximal Lipschitz solution $\{X_t^+, t \geq t_0\}$ to (2.3); it is adapted to the filtration $\mathcal{F}_t = \sigma(B_s, s \in [t_0, t])$.*

Haya Kaspi pointed out to us that measurability of a solution to (2.3) is the most delicate point of Theorem 2.2.

We will say that L_t^x is a local time for a process B_t if it is the occupation time density:

$$\int_{-\infty}^{\infty} h(x) L_t^x \, dx = \int_0^t h(B_t) \, dt, \qquad \text{a.s.},$$

for all h bounded and measurable. Note that if B_t is continuous and the local time L_t^x is jointly continuous, then $\sup_x L_t^x < \infty$, a.s. for each t.

We will use the traditional Markovian notation $\mathbb{P}^x$ to denote the distribution of $\{B_t, t \geq t_0\}$ conditioned by $\{B_{t_0} = x\}$, even though we do not assume the Markov property for B_t in Theorems 2.3 and 2.4 below.

Theorem 2.3. *Let $t_0 > 0$, $x_0, \beta_1, \beta_2 \in \mathbb{R}$. Assume that*

(i) the process B_t is continuous and has a jointly continuous local time L_t^x, and

(ii) if A_t is an adapted process with $A_{t_0} = x_0$ whose paths are Lipschitz continuous with Lipschitz constant M, then for each x the law of $\{B_t + A_t, t_0 \leq t \leq t_0 + s\}$ under $\mathbb{P}^x$ is mutually absolutely continuous with respect to the law of $\{B_t, t_0 \leq t \leq t_0 + s\}$ under $\mathbb{P}^{x+x_0}$, for every $s > 0$.

Then with probability one there exists a random $s_0 > 0$ and a unique Lipschitz solution to (1.1) on $[t_0, t_0 + s_0]$.

If in addition we assume that B_t is strong Markov then there is a unique Lipschitz solution to (1.1) for all $t \geq t_0$.

Remark 2.4. If W_t is a Brownian motion and f is a strictly increasing function such that both f and f^{-1} are Lipschitz continuous, it is easy to check that $B_t = f(W_t)$ is a strong Markov process that satisfies the other assumptions of Theorem 2.3.

Theorem 2.5. *Let $t_0, x_0 \in \mathbb{R}$. Assume that F_1 and F_2 are bounded, Lipschitz functions. Suppose that both are bounded by M and that both have Lipschitz constant less than or equal to M. Let B_t be a continuous process such that*

(i) there exist $c_1 > 0$ and $\gamma \in (0,1)$ such that whenever $s < t$,

$$\mathbb{P}(B_t \in dy \mid \mathcal{F}_s) \leq \frac{c_1}{(t-s)^\gamma}\, dy, \qquad y \in \mathbb{R}, \tag{2.4}$$

(ii) if A_t is an adapted process with $A_{t_0} = x_0$ whose paths are Lipschitz continuous with Lipschitz constant M, then for each x the law of $\{B_t + A_t, t_0 \leq t \leq t_0 + s\}$ under $\mathbb{P}^x$ is mutually absolutely continuous with respect to the law of $\{B_t, t_0 \leq t \leq t_0 + s\}$ under $\mathbb{P}^{x+x_0}$, for every $s > 0$.

Then with probability one, there exists a unique solution to (2.3) for all $t \geq t_0$.

We will show in Example 2.10 below that Theorem 2.5 applies to some fractional Brownian motions. As in Remark 2.4, some functions of fractional Brownian motions also satisfy the hypotheses of Theorem 2.5.

Let $f(x,b) = \beta_1 \mathbf{1}_{\{x \leq b\}} + \beta_2 \mathbf{1}_{\{x > b\}}$ and suppose that $\alpha_1 = \alpha_2 = 0$. Then (2.2) may be written as

$$X_t = x_0 + \int_{t_0}^t f(X_t, B_t) ds. \tag{2.5}$$

The function $(x,b) \to f(x,b)$ is discontinuous. In applications, such as that in Burdzy, Frankel, and Pauzner (1997), it may be argued that a model with continuous dX/dt might be more realistic. Let us replace f with a continuous approximation,

$$f_\varepsilon(x,b) = \beta_1 \mathbf{1}_{\{x < b-\varepsilon\}} + \beta_2 \mathbf{1}_{\{x > b+\varepsilon\}} + \left[\frac{\beta_2 - \beta_1}{2\varepsilon}(x - b + \varepsilon) + \beta_1 \right] \mathbf{1}_{\{b-\varepsilon \leq x \leq b+\varepsilon\}},$$

and consider the corresponding equation

$$X_t^\varepsilon = x_0 + \int_{t_0}^t f_\varepsilon(X_t^\varepsilon, B_t) ds. \tag{2.6}$$

We will show that the solutions to (2.6) converge to those of (2.5), and thus many results about solutions to (2.5) proved later in this article may be applied to give asymptotic results for the solutions to (2.6).

Theorem 2.6. *Assume that the equations (2.5) and (2.6) are defined relative to the same Brownian motion B_t. The equation (2.6) has a unique Lipschitz solution. As $\varepsilon \to 0$, the functions X_t^ε converge to the unique solution X_t of (2.5), a.s.*

Note that the convergence in Theorem 2.6 is uniform on compact sets as all functions X_t^ε are Lipschitz with constant $\max\{|\beta_1|, |\beta_2|\}$.

Remark 2.7. For the economics model behind (1.2), one does not necessarily want to require the Markov property to hold. The proof of Theorem 2.3 uses the strong Markov property to do an induction argument. For Theorem 2.5 we have in mind examples where B_t is a Gaussian process; see Example 2.10 below. In general, $B_{T+t} - B_T$ will not be Gaussian when T is a stopping time.

Example 2.8. We present an elementary example of a continuous deterministic function $t \to B_t$ for which there are multiple solutions to (1.1). Let $\beta_1 < 0$, $\beta_2 > 0$,

$$B_t = \begin{cases} (1+\beta_2)t & \text{for } t \in [0,1], \\ 1+\beta_2 & \text{for } t > 1, \\ 0 & \text{for } t < 0. \end{cases}$$

There are uncountably many solutions to (1.1) with this choice of B_t and the initial condition $X_0 = 1$. Here are two of them:

$$X_t^1 = \begin{cases} 0 & \text{for } t \le -1/\beta_2, \\ 1+\beta_2 t & \text{for } t > -1/\beta_2 \ ; \end{cases}$$

$$X_t^2 = \begin{cases} 0 & \text{for } t \le -1/\beta_2, \\ 1+\beta_2 t & \text{for } t \in (-1/\beta_2, 1] \\ 1+\beta_2 & \text{for } t \in (1,5], \\ 1+\beta_2+5\beta_1+\beta_1 t & \text{for } t > 5. \end{cases}$$

Example 2.9. As we noted earlier in this section, $X_t = B_t$ is a solution to (1.1) but a rather trivial one. In this example, we will show a less trivial and perhaps more interesting non-Lipschitz solution to (1.1). Take $\beta_1 = \beta_2 = 0$ in (1.1); in other words, consider the equation

$$\frac{dX_t}{dt} = 0 \qquad \text{if} \qquad X_t \neq B_t \qquad t \in \mathbb{R}, \qquad X(t_0) = x_0.$$

The function $X_t = 0$ is a solution to this equation and, moreover, it is the only Lipschitz solution, by Theorem 2.1. Let Y_t be a skew Brownian motion, i.e., a process which may be constructed by flipping positive excursions of a standard Brownian motion $\widetilde{B}_t$ to the negative side with probability p_1 and negative excursions to the positive side with probability p_2, independently of each other. Suppose that $p_1 \neq p_2$ so that the process Y_t is not a standard Brownian motion. Let L_t be the local time of Y_t at 0. By a result of Harrison and

Shepp (1981) (see also Exercise X (2.24) in Revuz and Yor (1991)), for a suitable constant $c_1 \neq 0$, the process $Y_t - c_1 L_t$ is a standard Brownian motion. If we take $B_t = Y_t - c_1 L_t$ then $X_t = c_1 L_t$ is a non-Lipschitz solution to our equation.

Example 2.10. We provide an example of a process satisfying the assumptions of Theorem 2.5 that is not strong Markov. Let B_t be fractional Brownian motion of index $H \in (0, 1/2]$. This means that B_t is a mean zero Gaussian process with

$$\mathrm{Cov}\,(B_s, B_t) = c_1(s^{2H} + t^{2H} - |t-s|^{2H}).$$

B_t has a stochastic integral representation

$$B_t = \int_{-\infty}^t R(t,u)\,dZ_u,$$

where Z_u is a standard Brownian motion and

$$R(t,u) = c_2[((t-u)^+)^{H-1/2} - (u^-)^{H-1/2}];$$

see, e.g., Rogers (1997). Conditioning on $\mathcal{F}_s$ with $s > 0$, the law of B_t given $\mathcal{F}_s$ is that of a Gaussian process with variance

$$c_2^2 \mathbb{E}\Big[\Big(\int_s^t (t-u)^{H-1/2}\,dZ_u\Big)^2 \mid \mathcal{F}_s\Big] = c_2^2 \int_s^t (t-u)^{2H-1}\,du = c_3(t-s)^{2H}.$$

Assumption (i) of Theorem 2.5 is immediate from this.

We now show (ii). We give the argument for the case $t_0 = x_0 = 0, s = 1$; the extension to the general case is routine.

If $H = 1/2$, then B_t is standard Brownian motion, and (ii) follows from the Girsanov theorem; so we suppose $H < 1/2$. Let $\alpha = H + 1/2$. See Decreusefond and Üstünel (1997) for more details of some of the steps in the following argument. Let $F(a, b, c, z)$ be the standard Gauss hypergeometric function and define an operator K_H on functions on $[0, 1]$ by

$$(K_H f)(t)$$
$$= \frac{1}{\Gamma(H+1/2)} \int_0^t (t-x)^{H-1/2} F(H-1/2, 1/2-H, H+1/2, 1-t/x) f(x)dx.$$

Let $\mathcal{H}_H = \{K_H h : h \in L^2([0,1])\}$ and define

$$\|f\|_{\mathcal{H}_H} = \|K_H^{-1} f\|_{L^2}.$$

For $\beta \in (0,1)$ define

$$(I^\beta f)(x) = \frac{1}{\Gamma(\beta)} \int_0^x f(t)(x-t)^{\beta-1} dt$$

and

$$(D^\beta f)(x) = \frac{d}{dx}\Big(I^{1-\beta} f\Big)(x).$$

By Decreusefond and Üstünel (1997) (Theorem 2.1, Theorem 3.3, and the proof of Theorem 3.3), we have that $\mathcal{H}_H$ is dense in the set of continuous functions on $[0,1]$ that are null at 0 and that K_H is an isomorphism from $L^2([0,1])$ onto $I^{H+1/2}(L^2([0,1]))$. By Proposition 2.1 of that paper, D^β is the inverse to I^β.

Since K_H^{-1} is continuous from $I^{H+1/2}(L^2)$ into L^2, then $K_H^{-1} \circ I^{H+1/2}$ is continuous from L^2 into itself, and so there exists a constant c_4 such that

$$\|K_H^{-1} I^{H+1/2} g\|_{L^2} \le c_4 \|g\|_{L^2}.$$

Thus if $f \in \mathcal{H}_H$, then

$$\|K_H^{-1} f\|_{L^2} \le c_4 \|D^{H+1/2} f\|_{L^2},$$

or

$$\|f\|_{\mathcal{H}_H} \le c_4 \|D^\alpha f\|_{L^2}.$$

Let A_t be a uniformly Lipschitz process as in the statement of Theorem 2.5. By Theorem 4.9 of Decreusefond and Üstünel (1997) and the Novikov condition discussed just after that theorem, (ii) will hold if for each $T \in (0,1)$ we have

$$\mathbb{E} \exp[\|A(\cdot)\|^2_{\mathcal{H}_H}/2] < \infty.$$

By the above paragraph, it is enough to show

$$\mathbb{E} \exp\Big(\int_0^T |D^\alpha A_t|^2 \, dt/2\Big) < \infty. \tag{2.7}$$

To show (2.7), by an approximation argument it suffices to show that for each fixed $T > 0$ there exists c_5 (depending on T) such that if f is a C^∞ function on $[0,\infty)$ with $f(0) = 0$, then

$$\sup_{0 \le t \le T} |D^\alpha f(x)| \le c_5 \|f'\|_\infty; \tag{2.8}$$

(2.7) will then follow easily from (2.8) and our assumptions on A_t.

Note that by a change of variables,

$$I^{1-\alpha}f(x) = c_6 \int_0^x f(x-t)t^{-\alpha}dt,$$

and by the Leibniz formula and the fact that $f(0) = 0$,

$$\frac{d}{dx}I^{1-\alpha}f(x) = c_6 \int_0^x f'(x-t)t^{-\alpha}dt = c_6 \int_0^x f'(t)(x-t)^{-\alpha}dt = I^{1-\alpha}f'(x).$$

Since $\alpha = H + 1/2 < 1$, then $|x-t|^{-\alpha}$ is integrable on $[0, x]$. So, for $u = f'$,

$$|D^\alpha f(x)| = |I^{1-\alpha}u(x)| \le \|u\|_\infty \int_0^x |x-t|^{-\alpha}\, dt \le c_7 \|u\|_\infty$$

for $x \le T$. This gives (2.8), and thus a fractional Brownian motion with parameter $H \in (0, 1/2]$ satisfies the assumptions of Theorem 2.5.

Example 2.11. The weaker version of Theorem 2.3, i.e., the one without the assumption on the Markov character of B_t, applies to fractional Brownian motions with parameter $H \in (0, 1/2]$. Assumption (ii) of Theorem 2.3 is the same as (ii) of Theorem 2.5; we have verified that assumption in the previous example. As for assumption (i) of Theorem 2.3, the joint continuity of the local time for the fractional Brownian motion follows from Lemma 8.8.1, Theorem 8.8.2 and the proof of Theorem 8.8.4 in Adler (1981).

Example 2.12. Fabes and Kenig (1981) gave an example of a process B_t satisfying

$$dB_t = \sigma(B_t, t)\, dW_t,$$

where W_t is a standard Brownian motion, σ is Hölder continuous in the first variable, σ is bounded above and below by positive constants, and the distribution of B_1 does not have a density with respect to Lebesgue measure. B_t is a space-time strong Markov process. Because σ is bounded below, it is not hard to see that B_t has a jointly continuous local time (cf. Revuz and Yor (1991), Ch. 6) and that hypothesis (ii) of Theorem 2.3 holds. Thus this process B_t is an example where the assumptions of Theorem 2.3 hold, but those of Theorem 2.5 do not.

The rest of the section contains proofs of our main results. The following lemma is immediate.

Lemma 2.13. *Let $\widetilde{B}_t = B_{-t}$ and $\widetilde{X}_t = X_{-t}$. If X_t is a solution to (2.1) then $\widetilde{X}_t$ is a solution to*

$$\frac{d\widetilde{X}}{dt} = \begin{cases} -\beta_1|\widetilde{X}_t - \widetilde{B}_t|^{\alpha_1} & \text{if } \widetilde{X}_t < \widetilde{B}_t, \\ -\beta_2|\widetilde{X}_t - \widetilde{B}_t|^{\alpha_2} & \text{if } \widetilde{X}_t > \widetilde{B}_t, \end{cases} \qquad t \in \mathbb{R}, \qquad \widetilde{X}(-t_0) = x_0.$$

Proof of Theorem 2.1. For simplicity, assume that $t_0 = 0$. The equation

$$Y_t = x_0 + \int_0^t \left[\beta_1|Y_s|^{\alpha_1}\mathbf{1}_{\{Y_s \le 0\}} + \beta_2|Y_s|^{\alpha_2}\mathbf{1}_{\{Y_s > 0\}}\right] ds - \int_0^t dB_s, \qquad t \ge 0,$$

has a weak solution which is unique in law by Theorem 5.15 in Karatzas and Shreve (1988). For $X_t = Y_t + B_t$, the last equation is equivalent to (2.2) for $t \ge 0$. This proves the first assertion of the theorem. The strong uniqueness in the case $\alpha_1, \alpha_2 \ge 0$ follows from Proposition 5.17 of Karatzas and Shreve (1988). We note that although the function $y \to y^\alpha$ is not bounded, that proposition clearly applies by using a truncation argument. The part of the solution to (2.1) for $t < t_0 = 0$ can be obtained in a similar way using Lemma 2.13. That X_t may be constructed so that (X_t, B_t) is a strong Markov process follows from the weak uniqueness in a standard manner; see Bass (1997), Section I.5, or Stroock and Varadhan (1979), Chapter 6. □

Proof of Theorem 2.2. We start by showing that for each ω and for any u_1 and z_1 there exists a maximal solution $\widetilde{X}_t^{u_1,z_1}$ to the equation

$$dX_t/dt = F_1(X_t), \qquad t \in \mathbb{R}, \qquad X(u_1) = z_1.$$

First of all, it is well known that there exists at least one solution to the equation since F_1 is continuous. Since $|F_1|$ is bounded by β, all solutions are Lipschitz with constant β and so their supremum $\widetilde{X}_t^{u_1,z_1}$ is also a Lipschitz function with constant β. Next note that the maximum of any two solutions is also a solution to the equation. This and the Lipschitz property of solutions easily imply that there exists a sequence of solutions converging to $\widetilde{X}_t^{u_1,z_1}$, uniformly on compact intervals. Now a standard argument can be used to show that $\widetilde{X}_t^{u_1,z_1}$ is a solution to the equation.

The analogous maximal solution to $dX_t/dt = F_2(X_t)$ with the initial condition $X(u_1) = z_1$ will be denoted $\widehat{X}_t^{u_1,z_1}$.

We start by proving the existence of a solution to (2.3) for $t \ge t_0$. Consider a small $\delta > 0$. We proceed to define a δ-approximate solution X_t^δ to (2.3). First suppose that

$B_{t_0} < x_0$. By the continuity of the paths of B_t, for almost every path of B_t, there exist a unique time $t_1 \in (t_0, \infty]$ and a function X^δ_t defined for $t \in (t_0, t_1)$, such that $X^\delta_{t_0} = x_0$, $X^\delta_{t_1} = B_{t_1}$ if $t_1 < \infty$, and $X^\delta_t = \widetilde{X}^{t_0,x_0}_t$ for all $t \in (t_0, t_1)$. We then let $X^\delta_t = X^\delta_{t_1} + \beta(t-t_1)$ for all $t \in [t_1, t_1+\delta]$, if $t_1 < \infty$. If $B_{t_0} > x_0$ we use the same procedure to define X^δ_t for $t \in [t_0, t_1+\delta]$ except that we use the function $\widehat{X}^{t_0,x_0}_t$ in place of $\widetilde{X}^{t_0,x_0}_t$. If $B_{t_0} = x_0$, we let $t_1 = t_0$ and $X^\delta_t = X^\delta_{t_1} + \beta(t-t_1)$ for $t \in [t_1, t_1+\delta]$.

We have defined X^δ_t on an interval $[t_0, t_1+\delta]$. Let $x_1 = X^\delta_{t_1+\delta}$. Let us replace the initial condition in (2.3) by $X(t_1+\delta) = x_1$ and define an approximate solution X^δ_t to (2.3) on an interval $[t_1+\delta, t_2+\delta]$ using the same method as above. By induction, we can construct a (possibly infinite) sequence of times $\{t_k\}$ and a continuous function X^δ_t which satisfies (2.3) on every interval $(t_k+\delta, t_{k+1})$ and which is linear on every interval $[t_k, t_k+\delta]$, for $k \geq 1$. Note that the function X^δ_t is defined for all $t \geq t_0$ because $t_{k+1} \geq t_k + \delta$ for every k.

By construction, the δ-approximate solution X^δ_t is a Lipschitz function with Lipschitz constant β.

For every integer $m \geq 1$ consider a $1/m$-approximate solution $X^{1/m}_t$. All of these functions are Lipschitz with the same constant β, and they all satisfy $X^{1/m}_{t_0} = x_0$. Let X_t be defined by

$$X_t = \limsup_{m\to\infty} X^{1/m}_t = \lim_{n\to\infty} \sup_{m>n} X^{1/m}_t.$$

The supremum of an arbitrary family of Lipschitz functions with constant β is a Lipschitz function with the same constant, and the same remark applies to the limit of a sequence of such functions. Hence, for every n, the function $Y^n_t = \sup_{m>n} X^{1/m}_t$ is Lipschitz with constant β, and the same is true of X_t. Note that Y^n_t converge in a monotone way to X_t, uniformly on compact intervals, because all these functions are Lipschitz with the same constant β.

We will show that X_t is a solution to (2.3). Let

$$W(\delta) = \bigcup_{\{(s,x): s \geq t_0, B_s = x\}} \{(t,y) : y = x + (t-s)\beta, t \in [s, s+\delta]\}.$$

For $\delta \leq \delta_1$, the portion of the graph of X^δ_t which lies outside $W(\delta_1)$ satisfies (2.3), by construction.

The set of t such that $B_t = X_t$ is closed because both functions B_t and X_t are continuous. Consider any interval (s_1, s_2) such that $B_t \neq X_t$ for all $t \in (s_1, s_2)$. Suppose without loss of generality that $B_t < X_t$ for all $t \in (s_1, s_2)$ Choose an arbitrarily small

$\delta_1 > 0$. Note that as $\delta \to 0$, the open sets $W^c(\delta)$ converge to the complement of $\{(s,x) : s \geq t_0, B_s = x\}$. Let $\delta_2 > 0$ be so small that the (closed) portion of the graph of X_t between $s_1 + \delta_1$ and $s_2 - \delta_1$ does not intersect $W(\delta_2)$. Let $s_0 = s_1 + \delta_1$. Since the Y^n_t converge to X_t, there exists a sequence m_j such that $X^{1/m_j}_{s_0} \to X_{s_0}$. For sufficiently large j, the point $(s_0, X^{1/m_j}_{s_0})$ lies outside $W(\delta_2)$ and we also have $1/m_j < \delta_2$. Then, for t in a neighborhood of s_0, the function X^{1/m_j}_t must be given by $X^{1/m_j}_t = \widetilde{X}^{s_0, X^{1/m_j}_{s_0}}_t$. We will show that $X_t = \widetilde{X}^{s_0, X_{s_0}}_t$ for $t \in (s_0, s_2 - \delta_1)$.

Suppose that this is not true and let $s_3 = \inf\{t \in [s_0, s_2 - \delta_1] : X_t \neq \widetilde{X}^{s_0, X_{s_0}}_t\}$. Since (s_3, X_{s_3}) lies outside $W(\delta_2)$, an argument similar to the one given above shows that for some $\delta_3, \delta_4 > 0$, and all $m > 1/\delta_2$, the functions $X^{1/m}_t$ must satisfy $X^{1/m}_t = \widetilde{X}^{s_3, X^{1/m}_{s_3}}_t$ for $t \in [s_3, s_3 + \delta_3]$, if $|X^{1/m}_{s_3} - X_{s_3}| \leq \delta_4$. A straightforward argument now implies that for large n, $Y^n_t = \widetilde{X}^{s_3, Y^n_{s_3}}_t$ for $t \in [s_3, s_3 + \delta_3]$, and this in turn proves that $X_t = \widetilde{X}^{s_3, X_{s_3}}_t$ for $t \in [s_3, s_3 + \delta_3]$. This contradicts the definition of s_3 and proves our claim.

Thus X_t satisfies (2.3) on $(s_1 + \delta_1, s_2 - \delta_1)$ and, in view of arbitrary nature of δ_1, the same claim extends to the whole interval (s_1, s_2). The argument applies to all intervals (s_1, s_2) such that $B_t \neq f(X_t)$ for all $t \in (s_1, s_2)$. This implies that X_t is a Lipschitz solution to (2.3). The proof of the existence of a Lipschitz solution is complete.

The existence of the solution to (2.3) for $t < t_0$ may be proved in a completely analogous way. The two solutions can be combined into one function X_t in an obvious way. It remains to check if the differential equation (2.3) is satisfied at $t = t_0$. It is easy to see that if $B_{t_0} < x_0$ then $dX_t/dt = F_1(X_t)$ for all t in some intervals $(t_0 - \delta, t_0)$ and $(t_0, t_0 + \delta)$ with $\delta > 0$. This and the continuity of X_t at $t = t_0$ evidently imply that $dX_t/dt = F_1(X_t)$ for $t = t_0$ and so (2.3) is satisfied for $t = t_0$. The case when $B_{t_0} > x_0$ is analogous. When $B_{t_0} = x_0$ then (2.3) is trivially satisfied by X_t for $t = t_0$.

Since the functions $\{X^{1/m}_t, t \geq t_0\}$ are adapted to the Brownian filtration $\mathcal{F}^B_t = \sigma(B_s, s \in [t_0, t])$, so is their lim sup, X_t. It follows that the process $\{(B_t, X_t), t \geq t_0\}$ is strong Markov with respect to the filtration $\{\mathcal{F}^B_t, t \geq t_0\}$.

We will show that the function $\{X_t, t \geq t_0\}$ constructed above is the largest of all Lipschitz solutions to (2.3), that is, if X^*_t is another Lipschitz solution, then $X_t \geq X^*_t$ for all $t \geq t_0$. Consider any Lipschitz solution X^*_t to (2.3) and suppose that $X^*_t > X_t$ for some $t \geq t_0$. Then there must exist $\delta = 1/m_j$ such that $X^*_t > X^\delta_t$ for some $t \geq t_0$. Fix such δ and let S be the infimum of those t such that $X^*_t > X^\delta_t$. If $S \in [t_j + \delta, t_{j+1})$ for some j, then $X^*_S = X^\delta_S \neq B_S$ a.s., and, by continuity, we must have $X^*_s \neq B_s$ and $X^\delta_s \neq B_s$ for all s in some non-degenerate interval $[S, S + \delta_1)$. On this interval one of the conditions in (2.3) is satisfied by both X_t^* and X_t^δ, so $X_s^* = X_s^\delta = \widetilde{X}^{S,X_S^*}$ for all $s \in [S, S+\delta_1)$ or $X_s^* = X_s^\delta = \widehat{X}^{S,X_S^*}$ for all $s \in [S, S+\delta_1)$. This contradicts the definition of S. Next suppose that $S \in [t_j, t_j+\delta)$ for some j. On this interval, the derivative of X_t^δ is equal to β. It is is easy to see that a Lipschitz solution X_t^* to (2.3) cannot grow faster than that on this interval, and so $S \geq t_j + \delta$, a contradiction which completes the proof of our claim.

A similar construction gives a solution $\{X_t, t \leq t_0\}$ to (2.3) which is maximal among all Lipschitz solutions on the interval $(-\infty, t_0]$ with constant β. Note that X_t is measurable with respect to the σ-field $\sigma(B_s, s \in [t, t_0])$ for $t < t_0$.

The maximal solution X_t of (2.3) is consistent in the following sense. Consider a fixed path $\{B_t, t \in \mathbb{R}\}$ and the corresponding maximal solution X_t. Now choose any $s > 0$ and suppose that $X_s = z$. Let $\{X_u^*, u \geq s\}$ be the largest Lipschitz solution with constant β for the equation (2.3) on the interval $[s, \infty)$ with the initial condition $X_s^* = z$ and the path $\{B_t, t \in \mathbb{R}\}$ truncated to $\{B_t, t \geq s\}$. Then it is easy to see that $X_u^* = X_u$ for all $u \geq s$. It follows that for $s \geq 0$, the portion $\{X_t, t \in [s, u]\}$ of the solution to (2.3) may be defined only in terms of X_s and $\{B_t, t \in [s, u]\}$.

In a similar fashion we can construct a minimal solution to (2.3); this minimal solution is also adapted to the filtration of B_t. Uniqueness would follow once we prove the maximal and minimal solutions are equal for all s a.s. $\square$

Proof of Theorem 2.3. Let X^+ and X_- be the maximal and minimal solutions to (1.1). By (2.3) the $\mathbb{P}^x$ law of $B_t - X^-(t)$ is mutually absolutely continuous with respect to the $\mathbb{P}^x$ law of B_t, so under $\mathbb{P}^x$, $B_t - X^-(t)$ has a jointly continuous local time $\widetilde{L}_t^x$ such that $\sup_x \widetilde{L}_t^x < \infty$, a.s. for each t.

Let

$$U(1) = \inf\{t > 0 : \sup_x \widetilde{L}_t^x \geq 1/(4\beta)\}.$$

If $t \leq U(1)$ and $a > 0$, then

$$\int_0^t 1_{(B_s - X^-(s) \in [0,a])} ds = \int_0^a \widetilde{L}_t^x \, dx \leq a/(4\beta).$$

Let $a > 0$ and

$$S = \inf\{t > 0 : X^+(t) - X^-(t) \geq a\}.$$

Since both X^+ and X^- satisfy (1.1), if $V = U(1) \wedge S$,

$$\begin{aligned} X^+(V) - X^-(V) &\le 2\beta \int_0^V 1_{(X^-(u) \le B_u \le X^+(u))} du \\ &\le 2\beta \int_0^t 1_{(0 \le B_u - X^-(u) \le X^+(u) - X^-(u))} du \\ &\le 2\beta \int_0^t 1_{(0 \le B_u - X^-(u) \le a)} du \\ &\le 2a\beta/(4\beta) = a/2. \end{aligned}$$

Since $X^+(V) - X^-(V) = a$ if $U(1) > S$, we must have $V = U(1)$. This is true for all $a > 0$, so $X^+(t) = X^-(t)$ for $t \le U(1)$.

Now assume that B_t is strong Markov and let $U(j+1) = U(j) + U(1) \circ \theta_{U(j)}$, $j = 1, 2, \ldots$, where θ is the shift operator associated with the process B_t. An induction argument using the strong Markov property at $U(j)$ shows that $X^+(t) = X^-(t)$ for $t \le U(j+1)$ for $j = 1, 2, \ldots$. The continuity of B_t and $\widetilde{L}_t^x$ easily implies $U(j) \to \infty$, a.s., so $X^+(t) = X^-(t)$ for all $t \ge t_0$. $\square$

The proof of Theorem 2.5 will be split into several lemmas.

For the remainder of the section, let $\delta = (1-\gamma)/4$. Note that $\delta \in (0, 1/4)$ since $\gamma \in (0,1)$. The constants $c_1, c_2, \ldots$, in the proofs in this section may depend on γ and δ.

Lemma 2.14. *Let $\alpha \ge 1$, $t \le 1$, $A > 0$, $C_t = \int_0^t 1_{(0 < B_s < As^\alpha)}\, ds$. Assume that condition (i) of Theorem 2.5 holds. There exist c_1 and c_2 independent of α and A such that for $\lambda > 0$,*

$$\mathbb{P}(C_t > \lambda) \le c_1 \exp(-c_2 \lambda \alpha^\delta / (At^{\alpha + 2\delta})).$$

Proof. First let us compute $\mathbb{E}(C_t - C_u \mid \mathcal{F}_u)$ for $u \in [0, t]$. Let $R = R(\alpha) = \alpha^{1/\alpha}$. Note that $R \ge 1$, $R = \exp(\alpha^{-1} \log \alpha) \le c_3$, and

$$1 - R^{-1} = 1 - \exp(-\log \alpha / \alpha) \le \log \alpha / \alpha \le c_4 \alpha^{-1/2},$$

where c_3 and c_4 do not depend on α as long as $\alpha \ge 1$.

By condition (i) of Theorem 2.5,

$$\begin{aligned} \mathbb{E}(C_t - C_u \mid \mathcal{F}_u) &= \int_u^t \mathbb{P}(B_s \in (0, As^\alpha) \mid \mathcal{F}_u)\, ds \\ &\le \int_u^t \frac{c_5 A s^\alpha}{(s-u)^\gamma}\, ds. \end{aligned}$$

Let us examine

$$I = \int_u^t \frac{s^\alpha}{(s-u)^\gamma}\, ds.$$

Suppose first that $u < t/R$. We observe, using the fact that $R \geq 1$,

$$\begin{aligned} \int_u^{t/R} \frac{s^\alpha}{(s-u)^\gamma}\, ds &\leq \Big(\frac{t}{R}\Big)^\alpha \int_u^{t/R} \frac{ds}{(s-u)^\gamma} \leq \frac{t^\alpha}{\alpha} \int_u^t \frac{ds}{(s-u)^\gamma} \\ &= \frac{t^\alpha}{\alpha} \int_0^{t-u} \frac{ds}{s^\gamma} \leq c_6 \frac{t^\alpha}{\alpha} t^{1-\gamma}. \end{aligned} \tag{2.9}$$

On the other hand, in view of the inequality $1 - R^{-1} \leq c_4 \alpha^{-1/2}$,

$$\begin{aligned} \int_{t/R}^t \frac{s^\alpha}{(s-u)^\gamma}\, ds &\leq t^\alpha \int_{t/R}^t \frac{ds}{(s-u)^\gamma} \\ &\leq t^\alpha \int_{t/R}^t \frac{ds}{(s-t/R)^\gamma} \\ &= t^\alpha \int_0^{t(1-1/R)} \frac{ds}{s^\gamma} \\ &= c_7 t^\alpha t^{1-\gamma} (1-R^{-1})^{1-\gamma} \\ &\leq c_8 t^{\alpha+1-\gamma}/\alpha^{(1-\gamma)/2}. \end{aligned}$$

Recalling that $\alpha \geq 1$ and combining with (2.9),

$$I \leq \frac{c_9 t^{\alpha-1-\gamma}}{\alpha^{(1-\gamma)/2}}.$$

Now suppose $u \geq t/R$. Then

$$\begin{aligned} \int_u^t \frac{s^\alpha}{(s-u)^\gamma}\, ds &\leq t^\alpha \int_u^t \frac{ds}{(s-u)^\gamma} = t^\alpha \int_0^{t-u} \frac{ds}{s^\gamma} \\ &= c_9 t^\alpha (t-u)^{1-\gamma} \leq c_9 t^\alpha (t - t/R)^{1-\gamma} \\ &= c_9 t^{\alpha+1-\gamma} (1-R^{-1})^{1-\gamma}. \end{aligned}$$

As before, this is less than or equal to $c_{10} t^{\alpha+1-\gamma}/\alpha^{(1-\gamma)/2}$.

Since $\delta = (1-\gamma)/4$, $t \leq 1$ and $\alpha \geq 1$,

$$\mathbb{E}(C_t - C_u \mid \mathcal{F}_u) \leq c_{11} A t^{\alpha+4\delta}/\alpha^{2\delta} \leq c_{11} A t^{\alpha+2\delta}/\alpha^\delta.$$

This says that almost surely the process $\mathbb{E}(C_t \mid \mathcal{F}_u)$ does not exceed C_u by more than $c_{11} A t^{\alpha+2\delta}/\alpha^\delta$ for any $u \leq t$. In particular,

$$\mathbb{E}(C_t - C_T \mid \mathcal{F}_T) \leq c_{11} A t^{\alpha+2\delta}/\alpha^\delta$$

for every stopping time T bounded by t. We apply Theorem I.6.11 of Bass (1995) to deduce that there exist c_{12} and c_{13} such that

$$\mathbb{E}\exp(c_{12}C_t\alpha^\delta/(At^{\alpha+2\delta}))\le c_{13}.$$

Our result easily follows from this estimate. $\square$

Lemma 2.15. *Given $\xi>0$, there exist c_1,c_2 such that if $\alpha\ge 1$, $A,B>0$, $B/A>\xi$, and $\beta=\alpha+\delta$, then*

$$\mathbb{P}(C_t\ge Bt^\beta \text{ for some } t\le 1/2)\le c_1\exp(-c_2B\alpha^\delta/A).$$

Proof. Let $t_k=2^{-1-k/\beta}$, $k=0,1,\ldots$. The process C_t is increasing. So if $C_t\ge Bt^\beta$ for some $t\le 1/2$, then for some $k\ge 1$ we must have $C_{t_{k-1}}\ge B(t_k)^\beta$. Hence

$$\begin{aligned}\mathbb{P}(C_t\ge Bt^\beta \text{ for some } t\le 1/2)&\le \mathbb{P}(C_{t_{k-1}}\ge B(t_k)^\beta \text{ for some } k\ge 1)\\&\le\sum_{k=1}^\infty \mathbb{P}(C_{t_{k-1}}\ge B(t_k)^\beta).\end{aligned}\tag{2.10}$$

Using Lemma 2.14, this is bounded by

$$\begin{aligned}&\sum_{k=1}^\infty c_3\exp\Big(-c_4B(t_k)^\beta\alpha^\delta/(At_{k-1}^{\alpha+2\delta})\Big)\\&\qquad=\sum_{k=1}^\infty c_3\exp\Big(-c_4\frac{B\alpha^\delta}{A}2^{-\beta-k-(-1-(k-1)/\beta)(\alpha+2\delta)}\Big)\\&\qquad=\sum_{k=1}^\infty c_3\exp\Big(-c_4\frac{B\alpha^\delta}{A}2^{k\delta/\beta+\delta-(\alpha+2\delta)/(\alpha+\delta)}\Big).\end{aligned}$$

Since $\alpha\ge 1$ and $\delta\in(0,1/4)$, the quantity $2^{\delta-(\alpha+2\delta)/(\alpha+\delta)}$ is bounded below and above by absolute constants, so the last displayed formula admits a bound

$$\begin{aligned}&\sum_{k=1}^\infty c_3\exp\Big(-c_5\frac{B\alpha^\delta}{A}2^{k\delta/\beta}\Big)\\&\qquad=c_3\exp\Big(-c_5\frac{B\alpha^\delta}{A}\Big)\sum_{k=1}^\infty\exp\Big(-c_5\frac{B}{A}\alpha^\delta(2^{k\delta/\beta}-1)\Big).\end{aligned}\tag{2.11}$$

The infinite sum in the last expression is bounded by

$$\begin{aligned}\sum_{k=1}^\infty\exp(-c_5\frac{B}{A}(2^{k\delta/\beta}-1))&\le\sum_{k=1}^\infty\exp\Big(-\frac{c_5Bk\delta\log 2}{A\beta}\Big)\\&\le\frac{1}{1-\exp(-c_5B\delta\log 2/(A\beta))}\\&\le c_6A\beta/B.\end{aligned}$$

Combining this with (2.10) and (2.11) we obtain

$$\begin{aligned}\mathbb{P}(C_t \geq Bt^\beta \text{ for some } t \leq 1/2) &\leq c_3 \exp\Big(-c_5 \frac{B\alpha^\delta}{A}\Big) c_6 A\beta/B \\ &= c_3 \exp\Big(-c_5 \frac{B\alpha^\delta}{A} + \log c_6 + \log(A/B) + \log(\alpha+\delta)\Big) \\ &\leq c_3 \exp\Big(-c_5 \frac{B\alpha^\delta}{A} + \log c_6 - \log \xi + \log 2 + \log \alpha\Big).\end{aligned}$$

The last expression is less than

$$c_7 \exp\Big(-c_8 \frac{B\alpha^\delta}{A}\Big)$$

for suitable c_7 and c_8 (depending on ξ and δ) and all $\alpha \geq 1$. □

Let X_t^+ and X_t^- be the maximal and minimal solutions to (2.3) constructed in in the proof of Theorem 2.2. Let $Y_t = X_t^+ - X_t^-$. We will show $Y_t = 0$, a.s. for $t \leq 1/2$.

Lemma 2.16. *For each s,*

$$\mathbb{P}(X_s^+ = B_s) = 0, \qquad \text{a.s.}$$

and similarly with X_s^+ replaced by X_s^-.

Proof. We know X_s^+ is a process whose paths are Lipschitz continuous. By assumption (ii) of Theorem 2.5, there exists a probability measure $\mathbb{Q}$ which is equivalent to $\mathbb{P}$ and such that the $\mathbb{Q}$ law of $B_s - X_s^+$ is the same as the $\mathbb{P}$ law of B_s. Then

$$\mathbb{Q}(X_s^+ = B_s) = \mathbb{Q}(B_s - X_s^+ = 0) = \mathbb{P}(B_s = 0).$$

This is equal to zero by (2.4). Since $\mathbb{P}$ and $\mathbb{Q}$ are equivalent, the lemma is proved. □

Lemma 2.17. *$Y_t = 0$, a.s. if $t \leq 1/2$.*

Proof. The process X_t^+ satisfies the equation

$$X_t^+ = x + \int_0^t [F_1(X_s^+) 1_{(X_s^+ > B_s)} + F_2(X_s^+) 1_{(X_s^+ < B_s)}]\, ds.$$

X_t^- satisfies a similar equation. Then, noting Lemma 2.16,

$$\begin{aligned}Y_t = &\int_0^t [F_1(X_s^+) - F_1(X_s^-)] 1_{(B_s < X_s^- \leq X_s^+)}\, ds \\ &+ \int_0^t [F_2(X_s^+) - F_2(X_s^-)] 1_{(X_s^- \leq X_s^+ < B_s)}\, ds \\ &+ \int_0^t [F_1(X_s^+) - F_2(X_s^-)] 1_{(X_s^- < B_s < X_s^+)}\, ds.\end{aligned}$$

Therefore

$$\begin{aligned} Y_t &\le M\int_0^t (X_s^+ - X_s^-)\,ds + 2M\int_0^t 1_{(X_s^- < B_s < X_s^+)}\,ds \\ &= M\int_0^t Y_s\,ds + 2M\int_0^t 1_{(0<B_s - X_s^- < X_s^+ - X_s^-)}\,ds \\ &= M\int_0^t Y_s\,ds + 2M\int_0^t 1_{(0<B_s - X_s^- < Y_s)}\,ds. \end{aligned} \tag{2.12}$$

Recall that we have assumed that F_j is bounded by M. Hence, the process Y_t is Lipschitz with constant $2M$. Since X_s^- has Lipschitz paths, there exists, by assumption (ii) of Theorem 2.5, a probability measure $\mathbb{Q}$ equivalent to $\mathbb{P}$ such that under $\mathbb{Q}$, $\{B_s - X_s^-, 0 \le s \le 1/2\}$ has the same law as $\{B_s, 0 \le s \le 1/2\}$ does under $\mathbb{P}$. So it suffices to show that for any Lipschitz process Y_s with constant M satisfying

$$Y_t \le M\int_0^t Y_s\,ds + 2M\int_0^t 1_{(0<B_s<Y_s)}\,ds, \tag{2.13}$$

we have

$$\mathbb{P}(Y_t \ne 0 \text{ for some } t \le 1/2) = 0.$$

Let

$$D(A,\alpha) = \{Y_s \ge A s^\alpha \text{ for some } s \le 1/2\}.$$

As Y is Lipschitz with $|Y_t| \le 2Mt$, then $D(3M,1) = \emptyset$. Let $\varepsilon > 0$ and let $\eta = 1/4$. We will choose $N \ge 1$ and $j_0 \ge 0$ in a moment. Let $A_j = N^j$ if $j \le j_0$ and $A_j = (1+\eta)^j N^{j_0}$ for $j > j_0$. Let $\alpha_j = 1 + j\delta$. We want an estimate on the probability of $D(A_{j+1}, \alpha_{j+1}) - D(A_j, \alpha_j)$. If $\omega \notin D(A_j,\alpha_j)$, then $Y_s \le A_j s^{\alpha_j}$ for all $s \le 1/2$, and so from (2.13), for $t \le 1/2$,

$$\begin{aligned} Y_t &\le M\int_0^t A_j s^{\alpha_j}\,ds + 2M\int_0^t 1_{(0<B_s<A_j s^{\alpha_j})}\,ds \\ &= \frac{M A_j t^{\alpha_j+1}}{\alpha_j + 1} + 2M\int_0^t 1_{(0<B_s<A_j s^{\alpha_j})}\,ds. \end{aligned} \tag{2.14}$$

Let $\xi = (1-\eta)/2M$ and let c_1 and c_2 be constants chosen as in Lemma 2.15 (depending on ξ). Find large j_0 so that

$$(1 + j_0\delta)^{\delta/2}/2M \ge 1, \tag{2.15}$$

$$\frac{M}{1 + j_0\delta} \le \eta(1+\eta), \tag{2.16}$$

and

$$c_1 \sum_{j=j_0}^{\infty} \exp(-c_2(1-\eta^2)(1+j\delta)^{\delta/2}) < \varepsilon/2. \tag{2.17}$$

Next choose N large so that

$$N \geq M/\eta \tag{2.18}$$

and

$$2j_0 c_1 \exp(-c_2(1-\eta)N/2M) < \varepsilon/2. \tag{2.19}$$

For $j \geq j_0$, we have

$$\frac{MA_j}{(\alpha_j+1)} \leq \eta A_{j+1}, \tag{2.20}$$

using (2.16). The same inequality holds for $j < j_0$ in view of (2.18).

In view of (2.14) and (2.20), for ω to be in $D(A_{j+1}, \alpha_{j+1}) - D(A_j, \alpha_j)$, we must have,

$$\begin{aligned}\int_0^t 1_{(0<B_s<A_j s^{\alpha_j})}\, ds &\geq Y_t/(2M) - \frac{A_j t^{\alpha_j+1}}{2(\alpha_j+1)} \\ &\geq A_{j+1} t^{\alpha_{j+1}}/(2M) - \frac{A_j t^{\alpha_j+1}}{2(\alpha_j+1)} \\ &\geq (1-\eta) A_{j+1} t^{\alpha_{j+1}}/(2M)\end{aligned} \tag{2.21}$$

for some $t < 1/2$. Recall that we set $\xi = (1-\eta)/2M$ and note that for all j we have $(1-\eta)A_{j+1}/(2MA_j) \geq \xi$. By Lemma 2.15, the probability that the inequality (2.21) holds is less than or equal to

$$c_1 \exp\Big(-c_2 \frac{(1-\eta)A_{j+1}}{2MA_j} \alpha_j^\delta\Big).$$

Using (2.15) and (2.17) for $j \geq j_0$, we obtain

$$c_1 \sum_{j=j_0}^{\infty} \exp\Big(-c_2 \frac{(1-\eta)A_{j+1}}{2MA_j} \alpha_j^\delta\Big) \leq c_1 \sum_{j=j_0}^{\infty} \exp(-c_2 \frac{1-\eta^2}{2M} (1+j_0\delta)^{\delta/2}(1+j\delta)^{\delta/2}\Big) < \varepsilon/2.$$

From (2.19),

$$\begin{aligned}c_1 \sum_{j=0}^{j_0-1} \exp\Big(-c_2 \frac{(1-\eta)A_{j+1}}{2MA_j} \alpha_j^\delta\Big) &\leq c_1 \sum_{j=0}^{j_0-1} \exp\Big(-c_2 \frac{(1-\eta)N}{2M}\Big) \\ &\leq 2j_0 c_1 \exp(-c_2(1-\eta)N/2M) < \varepsilon/2.\end{aligned}$$

Hence,

$$c_1 \sum_{j=0}^{\infty} \exp\Big(-c_2 \frac{(1-\eta)A_{j+1}}{2MA_j} \alpha_j^\delta\Big) \leq \varepsilon,$$

and so

$$\mathbb{P}\Big(\bigcup_{j=0}^{\infty} D(A_j,\alpha_j)\Big) \le \varepsilon.$$

If $\omega \notin \bigcup_{j=0}^{\infty} D(A_j,\alpha_j)$, then $Y_t(\omega) \le A_j t^{\alpha_j} \le (1+\eta)^j N^{j_0}(1/2)^{1+j\delta}$ for all $j \ge j_0$ and all $t \le 1/2$. Since $(1+\eta)(1/2) < 1$, letting $j \to \infty$ shows $Y_t(\omega) = 0$. Therefore

$$\mathbb{P}(Y_t \ne 0 \text{ for some } t \le 1/2) \le \varepsilon.$$

Since ε is arbitrary, this proves the lemma. $\square$

Proof of Theorem 2.5. By Lemma 2.17 we have $Y_t = 0$ a.s. for $t \le 1/2$. If we consider the law of $B_{t+1/2}$ given $\mathcal{F}_{1/2}$, it is not hard to see that assumptions (i) and (ii) of Theorem 2.5 apply to this process as well. So we apply the same argument to $X^+_{t+1/2}$ and $X^-_{t+1/2}$, and we obtain $Y_{t+1/2} = 0$ for $t \le 1/2$, or $Y_t = 0$ for $t \le 2(1/2)$. By an induction argument, we then have $Y_t = 0$ for all t, which proves uniqueness. $\square$

Proof of Theorem 2.6. The existence and strong uniqueness of solutions X^ε_t to (2.6) can be proved in the same way as in Theorem 2.1.

Consider any sequence $\varepsilon_n \downarrow 0$ and with a slight abuse of notation let $X^n_t = X^{\varepsilon_n}_t$. Since all functions $t \to X^n_t$ are Lipschitz with constant β, we may suppose, passing to a subsequence, if necessary, that X^n_t converge to a function X^∞_t. In order to finish the proof, it will suffice to show that $X^\infty_t = X_t$. Since the equation (2.5) has a unique solution a.s., it will be enough to show that if ω is not in the null set where uniqueness does not hold, then $X^\infty_t(\omega)$ is a solution to (2.5). The functions X^n_t are Lipschitz with constant β, so the same is true of X^∞_t. Let A be the set of times t such that $X^\infty_t = B_t$. The complement of the set A consists of a countable number of open intervals. Let $I = (t_1, t_2)$ be one of the intervals in the complement of A. Fix any $t_3 \in I$ and suppose without loss of generality that $X^\infty_{t_3} > B_{t_3}$. Choose some $t_4 \in (t_1, t_3)$ and $t_5 \in (t_3, t_2)$ and let a be the infimum of $X^\infty_t - B_t$ over $t \in (t_4, t_5)$. For sufficiently large n, we have $\varepsilon_n < a/3$ and $|X^n_t - X^\infty_t| < a/3$ for all $t \in (t_4, t_5)$. It follows that for large n and $t \in (t_4, t_5)$, we have $X^n_t - B_t > a/3 > \varepsilon_n$. Hence, for such n and t, $dX^n_t/dt = \beta_2$. This shows that $dX^\infty_t/dt = \beta_2$ for all $t \in I$. The same argument works for all other intervals in the complement of A. There is nothing to check for $t \in A$, so X^∞_t is a solution to (2.5). $\square$

3. Local time. In the remaining part of the article we assume that B_t is a Brownian motion. In this section we will exclusively deal with solutions to (1.1). We will find several explicit formulae for the local time spent by B_t on the paths of the process X_t. Moreover, we will prove analogues of the Trotter and Ray-Knight theorems. The results on local times provide information about the behavior of the function $y \to X_t^y$, for fixed t; see Remark 3.9.

The first part of the section deals with exit systems. Some of our results on exit systems may be of independent interest. We refer the reader to Blumenthal (1992), Burdzy (1987), Maisonneuve (1975) or Sharpe (1989) concerning the fundamentals of excursion theory.

In this section, we will assume that $t_0 = 0$ and study the portion of the solution X_t to (1.1) for $t \geq 0$ only.

Let $D = \{(b, x) \in \mathbb{R}^2 : b = x\}$. We will construct an exit system (H^x, dL) for the process of excursions of (B_t, X_t) from the set D. The first element of an exit system is a family of excursion laws H^x. An excursion law H^x is an infinite σ-finite measure on the space C^* of functions (e_t^1, e_t^2) defined on $(0, \infty)$ (note that 0 is excluded) which take values in $\mathbb{R}^2 \cup \{\Delta\}$. Here Δ is the coffin (absorbing) state. Let ν be the lifetime of an excursion, i.e., $\nu = \inf\{t > 0 : (e_t^1, e_t^2) = \Delta\}$. Then H^x-a.e., we have $(e_t^1, e_t^2) \in \mathbb{R}^2$ for $t \in (0, \nu)$ and $(e_t^1, e_t^2) = \Delta$ for $t \in [\nu, \infty)$. The measure H^x is strong Markov with respect to the transition probabilities of the process $\{(B_t, X_t), t \geq 0\}$ killed at the hitting time of D. Moreover, the H^x-measure of the set of paths for which $\lim_{t \downarrow 0}(e_t^1, e_t^2) \neq (x, x)$ is equal to 0. The second element of the exit system, dL, denotes the measure defined by a non-decreasing process L_t. The process L_t is a continuous additive functional, also known as a local time, for (B_t, X_t) on D. The process L_t does not increase on any interval (s, u) such that $(B_t, X_t) \notin D$ for $t \in (s, u)$; that is, $L_s = L_u$ for such intervals. Consider a maximal interval (s, u) such that $B_t \neq X_t$ for $t \in (s, u)$. Suppose $L_s = r$. Let $(e_t^1, e_t^2)_r = (B_{s+t}, X_{s+t})$ for $t \in (0, u - s)$ and $(e_t^1, e_t^2)_r = \Delta$ for $t \geq u - s$. Let $\mu(r) = \inf\{t > 0 : L_t = r\}$. The collection of all "excursions" $\{(r, (e_\cdot^1, e_\cdot^2)_r)\}$ is a Poisson point process which, roughly speaking, has random mean measure $(r_2 - r_1) \int_{r_1}^{r_2} H^{\mu(r)}(A) dr$ on the set $(r_1, r_2) \times A$.

Next we apply some transformations to the excursions and excursion laws in order to simplify our description of the exit system. First, we note that by the translation invariance of the Brownian motion B_t and equation (1.1), the distribution of $(e_t^1 - x, e_t^2 - x)$ under H^x is the same for every $x \in \mathbb{R}$. Let this distribution be called H_1. For H_1-almost all excursions, the second component e_t^2 is a linear function of t until the excursion lifetime

ν, with the slope equal to β_1 or β_2. In the first case, $e^1_t > e^2_t$ for $t \in (0, \nu)$, while the inequality goes the other way in the second case. Let H_{1+} denote the part of the measure H_1 which is supported on excursions with $e^1_t > e^2_t$ and let H_{1-} be the part supported on the set where $e^1_t < e^2_t$. Let H_{2+} be the distribution of $\{e^1_t - e^2_t, t \in (0, \nu)\}$ under H_{1+} and let H_{2-} have the same definition relative to H_{1-}. Note that, by definition, the excursion laws H_{2+} and H_{2-} are supported on paths in $\mathbb{R} \cup \{\Delta\}$ rather than $\mathbb{R}^2 \cup \{\Delta\}$, since the second component becomes irrelevant after our last transformation.

Our transformations preserve the strong Markov property, but the last transformation creates a drift so that the measure H_{2+} has the transition probabilities of Brownian motion with drift $-\beta_1$, killed upon hitting 0. It is standard to show (see, e.g., Theorem 4.1 of Burdzy (1987)) that for any event A defined in terms of the process after some fixed time $s_0 > 0$, we have, up to a multiplicative constant,

$$H_{2+}(A) = \lim_{x \downarrow 0} \frac{1}{|x|} Q^x_{-\beta_1}(A), \tag{3.1}$$

where $Q^x_{-\beta_1}$ stands for the distribution of Brownian motion with drift $-\beta_1$, killed at the hitting time of 0. The normalization of the excursion laws is arbitrary as long as it matches the normalization of the local time, so we can use the normalization in (3.1). We next choose the normalization of the local time so that it matches that of H_{2+}. Given the normalization for H_{2+}, the normalization for H_{2-} is no longer arbitrary and we will have to prove that

$$H_{2-}(A) = \lim_{x \uparrow 0} \frac{1}{|x|} Q^x_{-\beta_2}(A). \tag{3.2}$$

Unless specified otherwise, all excursion laws in this paper will be normalized as in (3.1) or (3.2).

Let H_3 denote the excursion law for excursions of Brownian motion without drift away from 0. Let us split H_3 into positive and negative parts H_{3+} and H_{3-}, as in the case of H_2. We normalize H_3 using a formula analogous to (3.1). Recall that ν denotes the lifetime of an excursion e, and that (3.1) defines the normalization of H_{2+}.

Lemma 3.1. *(i) On the set where $\nu < \infty$,*

$$\frac{dH_{2+}}{dH_{3+}}(e) = \exp(-\beta_1^2 \nu / (2\sigma^2)).$$

(ii) For a fixed time $s \in (0, \infty)$, the conditional distributions of H_{2+} and H_{3+} given $\{\nu = s\}$ are identical.

(iii) If $\beta_1 < 0$ *then* $H_{2+}(\nu = \infty) = 2|\beta_1|/\sigma^2$.

(iv) Formula (3.2) is the correct normalization for H_{2-}.

Parts (i)-(iii) of Lemma 3.1 have obvious analogues for H_{2-}.

Proof. Fix arbitrary $0 < s_0 < s_1 < \infty$ and let A be an event measurable with respect to $\sigma\{e_t, t \in (s_0, s_1)\}$. Since H_{3+} is assumed to be normalized using a formula analogous to (3.1), we have

$$\frac{H_{2+}(A \cap \{\nu = s_1\})}{H_{3+}(A \cap \{\nu = s_1\})} = \lim_{x \downarrow 0} \frac{Q^x_{-\beta_1}(A \cap \{\nu = s_1\})}{Q^x_0(A \cap \{\nu = s_1\})}.$$

An application of Girsanov's Theorem, as in Karatzas and Shreve (1988) ((5.11), p. 196), shows that

$$\frac{Q^x_{-\beta_1}(A \cap \{\nu = s_1\})}{Q^x_0(A \cap \{\nu = s_1\})} = \exp(x\beta_1/\sigma^2 - \beta_1^2 s_1/(2\sigma^2)).$$

This and the previous formula imply

$$\frac{H_{2+}(A \cap \{\nu = s_1\})}{H_{3+}(A \cap \{\nu = s_1\})} = \exp(-\beta_1^2 s_1/(2\sigma^2)),$$

which then easily implies (i) and (ii).

As for (iii), we start with the formula

$$Q^x_{-\beta_1}(\nu = \infty) = 1 - \exp(2x\beta_1/\sigma^2),$$

with $\beta_1 < 0$ (Karlin and Taylor (1975), p. 362). Then (3.1) yields

$$H_{2+}(\nu = \infty) = \lim_{x \downarrow 0} \frac{1}{|x|} Q^x_{-\beta_1}(\nu = \infty) = 2|\beta_1|/\sigma^2,$$

as desired.

It remains to prove (iv). Fix arbitrarily small $\gamma > 0$ and let

$$A_1 = A_1(t) = \{\max_{s \le t} |X_s| > t^{1/2+\gamma}\}.$$

Note that $|X_t| \le \beta t < t^{1/2+\gamma}$ for small $t > 0$ so we have $\mathbb{P}(A_1(t)) = 0$ if t is small. However, we will prove the result using only the property that $\lim_{t \to 0} \mathbb{P}(A_1(t)) = 0$ because we will need this version of the proof later in the paper. Let us take $t_0 = 0$ and $x_0 = 0$ so that $X_0 = 0$. Note that the excursion law normalization does not depend on t_0 and x_0. Let $A_+ = A_+(s)$ be the event that the first excursion (e^1_t, e^2_t) of (B_t, X_t) from D with the property that $|e_t^1 - e_t^2| > s^{1/2+\gamma/2}$ for some $t \in (0, \nu)$, also has the property that $e_t^1 > e_t^2$ for $t \in (0, \nu)$. Let A_- be the analogous event with $e_t^1 < e_t^2$. Let $T(a)$ be the hitting time of a by B_t. For small $s > 0$,

$$\{T(s^{1/2+\gamma/2} + s^{1/2+\gamma}) < T(-s^{1/2+\gamma/2} + s^{1/2+\gamma}) < s\} \subset A_+(s) \cup A_1(s),$$

and

$$\{T(-s^{1/2+\gamma/2} - s^{1/2+\gamma}) < T(s^{1/2+\gamma/2} - s^{1/2+\gamma}) < s\} \subset A_-(s) \cup A_1(s).$$

It is elementary to check that

$$\begin{aligned}&\lim_{s\to 0} \mathbb{P}(T(s^{1/2+\gamma/2} + s^{1/2+\gamma}) < T(-s^{1/2+\gamma/2} + s^{1/2+\gamma}) < s) \\ &\qquad = \lim_{s\to 0} \mathbb{P}(T(-s^{1/2+\gamma/2} - s^{1/2+\gamma}) < T(s^{1/2+\gamma/2} - s^{1/2+\gamma}) < s) = 1/2.\end{aligned}$$

This and the fact that $\lim_{t\to 0} \mathbb{P}(A_1(t)) = 0$ imply that

$$\lim_{s\to 0} \mathbb{P}(A_+(s)) = \lim_{s\to 0} \mathbb{P}(A_-(s)) = 1/2. \tag{3.3}$$

The scale function $S(y)$ for Brownian motion with drift $-\beta_1$ is given by $S(y) = \exp(2\beta_1 y/\sigma^2)$ (Karlin and Taylor (1981) Chapter 15.4). Let F_h be the event that the difference between the maximum and the minimum of an excursion exceeds h. Then, by (3.1),

$$\begin{aligned}H_{2+}(F_h) &= \lim_{x\downarrow 0} \frac{1}{x} Q^x_{-\beta_1}(T_h < T_0) = \lim_{x\downarrow 0} \frac{1}{x} \cdot \frac{S(x) - S(0)}{S(h) - S(0)} \\ &= \lim_{x\downarrow 0} \frac{1}{x} \cdot \frac{\exp(2\beta_1 x/\sigma^2) - 1}{\exp(2\beta_1 h/\sigma^2) - 1} = \frac{2\beta_1}{\sigma^2} \cdot \frac{1}{\exp(2\beta_1 h/\sigma^2) - 1}.\end{aligned}$$

An analogous formula holds for $H_{2-}(F_h)$, but we will write it with an additional multiplicative constant c_1, since we have not proved that (3.2) is the right normalization yet:

$$H_{2-}(F_h) = c_1 \frac{2\beta_2}{\sigma^2} \cdot \frac{1}{\exp(2\beta_2 h/\sigma^2) - 1}.$$

Our goal is to show that $c_1 = 1$ is the correct choice for the constant.

Excursion theory tells us that the arrival times for excursions (e_t^1, e_t^2) of (B_t, X_t) from D with the property that $|e_t^1 - e_t^2| > s^{1/2+\gamma/2}$ for some $t \in (0, \nu)$, and with $e_t^1 > e_t^2$ for $t \in (0, \nu)$, form a Poisson point process on the local time scale with intensity $H_{2+}(F_{s^{1/2+\gamma/2}})$. This process is independent from the analogous process of excursions with $e_t^1 < e_t^2$. Formula (3.3) tells us that for small s, the probability that the first arrival for the first process is earlier than the first arrival for the second process is close to 1/2. Hence, the ratio of the intensities for the two Poisson point processes must converge to 1 as $s \to 0$. Therefore, we must have

$$\lim_{s\to 0} \frac{2\beta_1}{\sigma^2} \cdot \frac{1}{\exp(2\beta_1 s^{1/2+\gamma/2}/\sigma^2) - 1} \cdot \left(c_1 \frac{2\beta_2}{\sigma^2} \cdot \frac{1}{\exp(2\beta_2 s^{1/2+\gamma/2}/\sigma^2) - 1} \right)^{-1} = 1.$$

However, this is possible only if $c_1 = 1$. This completes the proof of (iv). □

Remark 3.2. (i) Lemma 3.1 (iv) can be used to prove uniqueness for (1.1). In order to do so, one would have to consider an exit system for the maximal Lipschitz solution X_t to (1.1), constructed as in the proof of Theorem 2.2, and the analogous exit system for the minimal Lipschitz solution. Lemma 3.1 (iv) shows that both exit systems are identical but this can be true only if the maximal and minimal solutions are the same. We will not formalize this argument as it cannot be easily generalized to non-Markov processes. The delicate part of the argument would be to show that the maximal solution X_t is the sum of the excursions and it contains no component corresponding to a "push" proportional to local time.

(ii) According to Lemma 3.1 (i)-(iii), if $\beta_1 < 0$, the excursion laws $H^{\beta_1}_{2+}$ and $H^{-\beta_1}_{2+}$ agree on the set of excursions with finite lifetime and the only difference is that $H^{\beta_1}_{2+}$ gives some mass to excursions with infinite lifetime, while $H^{-\beta_1}_{2+}$ does not.

For every $x \in \mathbb{R}$ consider the solution X^x_t to (1.1) with $X^x_0 = x$. Let L^x_t denote the local time of $Y^x_t \overset{\text{df}}{=} B_t - X^x_t$ at 0, defined earlier in this section as the local time of (B_t, X^x_t) on the diagonal, accumulated between times 0 and t. Note that this is not the local time of a one-dimensional diffusion at level x.

Proposition 3.3 *If* $\beta_1 > 0$ *and* $\beta_2 < 0$ *then for every* $x \in \mathbb{R}$,

$$\lim_{t\to\infty} L^x_t/t = \left(\frac{1}{|\beta_1|} + \frac{1}{|\beta_2|} \right)^{-1}, \qquad \text{a.s.}$$

Proof. Fix some $x \in \mathbb{R}$. Our assumptions that $\beta_1 > 0$ and $\beta_2 < 0$ imply that there will never be an excursion of B_t from X^x_t with infinite lifetime, since the drift will always push the excursions of Y^x_t towards 0. This in turn implies that L^x_t will grow to infinity a.s.

Recall that we used $Q^y_{-\beta_1}$ to denote the distribution of Brownian motion with drift $-\beta_1$, killed at the hitting time of 0. By Theorem 7.5.3 of Karlin and Taylor (1975), we have for $y > 0$,

$$Q^y_{-\beta_1}(\nu \in dt) = \frac{|y|}{\sigma t^{3/2}\sqrt{2\pi}} \exp\left(-\frac{(|y| - |\beta_1|t)^2}{2\sigma^2 t}\right) dt,$$

where ν denotes the lifetime of the process. The same formula holds for $y < 0$, with β_1 replaced by β_2. Using (3.1)-(3.2) we obtain

$$\begin{aligned} H_2(\nu \in dt) &= \lim_{y\downarrow 0} \frac{1}{|y|} Q^y_{-\beta_1}(\nu \in dt) + \lim_{y\uparrow 0} \frac{1}{|y|} Q^y_{-\beta_2}(\nu \in dt) \\ &= \lim_{y\downarrow 0} \frac{1}{\sigma t^{3/2}\sqrt{2\pi}} \exp\left(-\frac{(|y| - |\beta_1|t)^2}{2\sigma^2 t}\right) dt + \lim_{y\uparrow 0} \frac{1}{\sigma t^{3/2}\sqrt{2\pi}} \exp\left(-\frac{(|y| - |\beta_2|t)^2}{2\sigma^2 t}\right) dt \\ &= \frac{1}{\sigma t^{3/2}\sqrt{2\pi}} \exp[-(\beta_1^2/2\sigma^2)t]dt + \frac{1}{\sigma t^{3/2}\sqrt{2\pi}} \exp[-(\beta_2^2/2\sigma^2)t]dt. \end{aligned}$$

Let V^x_s be the inverse local time, i.e., $V^x_s = \inf\{t > 0 : L^x_t > s\}$. The process V^x_s is the sum of lifetimes of excursions which start before the local time reaches the level s. The Poisson character of the excursion process easily implies that

$$\begin{aligned} \mathbb{E}V^x_s &= s\int_0^\infty tH_2(\nu \in dt) \\ &= s\int_0^\infty t\frac{1}{\sigma t^{3/2}\sqrt{2\pi}} \exp[-(\beta_1^2/2\sigma^2)t]dt + s\int_0^\infty t\frac{1}{\sigma t^{3/2}\sqrt{2\pi}} \exp[-(\beta_2^2/2\sigma^2)t]dt \\ &= \left(\frac{1}{|\beta_1|} + \frac{1}{|\beta_2|}\right) s. \end{aligned} \tag{3.4}$$

This and the strong law of large numbers for the Lévy process $s \to V^x_s$ (see p. 92 of Bertoin (1996)) imply that

$$V^x_s/s \to \frac{1}{|\beta_1|} + \frac{1}{|\beta_2|},$$

a.s., as $s \to \infty$. This can be easily translated to the statement of the proposition. □

We note that if $\beta_1, \beta_2 > 0$, then we will eventually have $X^x_t > B_t$, for every x. Hence, in this case, $L^x_\infty < \infty$ for every $x \in \mathbb{R}$, a.s. We will prove the next lemma under the assumption that $\beta_1 - \beta_2 > 0$. We believe that similar statements hold when $\beta_1 - \beta_2 < 0$ but technical difficulties prevent us from giving a formal proof in that case.

The following lemma contains the most complicated and technical argument in the whole article.

Lemma 3.4. *(i) Fix $x, a, \beta_1, \beta_2 \geq 0$ and assume that $\beta_1 - \beta_2 > 0$. Then*

$$\mathbb{E}(L_\infty^{x+\delta} \mid L_\infty^x = a) = a - \delta \frac{\beta_1}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)) + o(\delta),$$

for $\delta \downarrow 0$.

(ii) If $a, \beta_1, \beta_2 \geq 0$, $x \leq 0$, and $\beta_1 - \beta_2 > 0$ then

$$\mathbb{E}(L_\infty^{x+\delta} \mid L_\infty^x = a) = a + \delta \left[\frac{\beta_2}{\beta_1 - \beta_2} - \frac{\beta_1}{\beta_1 - \beta_2} \exp(-2a(\beta_1 - \beta_2)/\sigma^2) \right] + o(\delta),$$

for $\delta \uparrow 0$.

Proof. (i) Recall that $B_0 = 0$, that we have fixed $x, a, \beta_1, \beta_2 \geq 0$ and assumed that $\beta_1 - \beta_2 > 0$. Since the proof of the lemma is quite long, we will split it into several steps.

Step 1. We start with some transformations of the processes X_t^x and B_t which will enable us to look at L_∞^x from a slightly different perspective. It is perhaps not necessary to make these transformations, but we find the transformed problem much easier to comprehend than the original one from an intuitive point of view.

We first offer a rough guide to our notation (whose validity is limited to this proof). Different Brownian motions with different drifts and reflected barriers will be denoted B_t^j, for $j = 1, 2, \ldots$. The notation L_t^{j-} and L_t^{j+} will refer to the local time of B_t^j on the lower and upper reflected barriers (if any). We will write $v_j(a) = \inf\{t : L_t^{j-} = a\}$.

It is well known that the set $\{t : B_t = 0\}$ has zero Lebesgue measure, so the Girsanov theorem implies that the same is true of the set $\{t : X_t^x = B_t\}$. We will excise all intervals where $X_t^x > B_t$. First, we define a clock $\mathcal{C}_1(t) = \int_0^t \mathbf{1}_{\{X_s^x \leq B_s\}} ds$ and its inverse $b_1(t) = \inf\{s : \mathcal{C}_1(s) \geq t\}$. Since $\beta_1, \beta_2 > 0$, we will eventually have $X_t^x > B_t$, so we let $u_1 = \sup\{\mathcal{C}_1(t) : t \geq 0\}$. Then we define new processes on the random interval $[0, u_1]$ by

$$\begin{aligned}
B_t^1 &= B_{b_1(t)} - \beta_2(b_1(t) - t), \\
X_t^{1,x} &= X_{b_1(t)}^x - \beta_2(b_1(t) - t), \\
X_t^{1,x+\delta} &= X_{b_1(t)}^{x+\delta} - \beta_2(b_1(t) - t).
\end{aligned}$$

For $t \in [0, u_1]$, we have $X_t^{1,x} = x + \beta_1 t$, the process B_t^1 is a Brownian motion staying above and reflected on the line $t \to x + \beta_1 t$, and the process $X_t^{1,x+\delta}$ is a solution to (1.1) with B_t replaced by B_t^1.

Next we similarly excise the intervals where $X_t^{1,x+\delta} < B_t^1$. Let us define a new clock $\mathcal{C}_2(t) = \int_0^t \mathbf{1}_{\{X_s^{1,x+\delta} \geq B_s^1\}} ds$, its inverse $b_2(t) = \inf\{s : \mathcal{C}_2(s) > t\}$, a random time $u_2 = \sup\{\mathcal{C}_2(t) : t \geq 0\}$, and processes

$$\begin{aligned} B_t^2 &= B_{b_2(t)}^1 - \beta_1(b_2(t) - t), \\ X_t^{2,x} &= X_{b_2(t)}^{1,x} - \beta_1(b_2(t) - t), \\ X_t^{2,x+\delta} &= X_{b_2(t)}^{1,x+\delta} - \beta_1(b_2(t) - t). \end{aligned}$$

For $t \in [0, u_2]$, we have $X_t^{2,x} = x + \beta_1 t$ and $X_t^{2,x+\delta} = x + \delta + \beta_2 t$. The process $\{B_t^2, t \in [0, u_2]\}$ is a Brownian motion reflected on the lines $t \to x + \beta_1 t$ and $t \to x + \delta + \beta_2 t$ and confined to the region between them. Note that $B_0^2 = x$ a.s. and that the lines $t \to x + \beta_1 t$ and $t \to x + \delta + \beta_2 t$ intersect at $t = \delta/(\beta_1 - \beta_2)$ so necessarily $u_2 \leq \delta/(\beta_1 - \beta_2)$.

The time u_2 corresponds to the start of the infinite excursion of B_t below the graph of X_t^x. By excursion theory and Lemma 3.1 (iii), the distribution of $L_{u_2}^x$ is exponential with mean $\sigma^2/(2\beta_2)$. Hence, we may assume that the process B_t^2 is generated in the following way. Suppose that B_t^3 is a Brownian motion starting from $B_0^3 = x$, reflected on the lines $t \to x + \beta_1 t$ and $t \to x + \delta + \beta_2 t$ and confined to the region between them, but defined for all $t \in [0, \delta/(\beta_1 - \beta_2))$ rather than confined to some random time interval. Let L_t^{3-} be the local time of B_t^3 on the line $t \to x + \beta_1 t$ and let Z be an exponential random variable with mean $\sigma^2/(2\beta_2)$, independent of B_t^3. If $v_3(s) = \inf\{t : L_t^{3-} = s\}$, then the distributions of the processes $\{B_t^2, t \in [0, u_2]\}$ and $\{B_t^3, t \in [0, v_3(Z)]\}$ are the same.

Let L_t^{3+} be the local time of B_t^3 accumulated on the line $t \to x + \delta + \beta_2 t$. The distribution of $L_\infty^{x+\delta}$ given $\{L_\infty^x = a\}$ is the same as the distribution of $L_{v_3(a)}^{3+}$, so we will try to find an approximate formula for $\mathbb{E} L_{v_3(a)}^{3+}$.

We continue our transformations. Let $B_t^4 = B_t^3 - x - \beta_1 t$. The process B_t^4 is a Brownian motion starting from 0, with drift $-\beta_1$, reflected on the horizontal axis and the line $t \to \delta - (\beta_1 - \beta_2)t$. The processes L_t^{3-} and L_t^{3+} can be identified with the local times L_t^{4-} and L_t^{4+} of B_t^4 on the horizontal axis and the line $t \to \delta - (\beta_1 - \beta_2)t$, resp. Hence, it will suffice to show that the estimate given in part (i) of the lemma holds for $\mathbb{E} L_{v_4(a)}^{4+}$.

Step 2. In this step we will obtain some estimates for reflected Brownian motions using excursion theory. Let B_t^5 be a Brownian motion with drift $-\beta_1$, confined to positive values by reflection on the horizontal axis. The Green function $G(z, y)$ for Brownian motion with drift $-\beta_1$, killed upon hitting 0 is given by

$$G(z, y) = \frac{1}{\beta_1} \left[\exp\left(\frac{2\beta_1 z}{\sigma^2} \right) - 1 \right] \exp\left(-\frac{2\beta_1 y}{\sigma^2} \right),$$

for $0 < z < y < \infty$, by (3.15) in Section 15.3 and Section 15.4.B of Karlin and Taylor (1981). Let $G^5_H(y)$ denote the Green function for the excursion law H_5 of B^5_t from 0, i.e., the function defined by

$$H_5 \left(\int_0^\infty \mathbf{1}_{\{e(t)\in[z_1,z_2]\}} dt \right) = \int_{z_1}^{z_2} G^5_H(y)dy.$$

A formula analogous to (3.1) yields

$$G^5_H(y) = \lim_{z\downarrow 0} \frac{1}{z} G(z,y) = \frac{2}{\sigma^2} \exp\left(-\frac{2\beta_1 y}{\sigma^2} \right),$$

for $y > 0$.

Consider some $\delta_1 > 0$ and excise excursions of B^5_t above the level δ_1, just as we did with the excursions of B_t and B^1_t. Let $\mathcal{C}_3(t) = \int_0^t \mathbf{1}_{\{B^5_s \le \delta_1\}} ds$, $b_3(t) = \inf\{s : \mathcal{C}_3(s) > t\}$, and $B^6_t = B^5_{b_3(t)}$. The process B^6_t is a reflected Brownian motion in $[0, \delta_1]$. Let $G^6_H(y)$ be the Green function for the excursion law H_6 of B^6_t from 0. It is clear from the nature of the transformation which generates B^6_t from the paths of B^5_t that $G^6_H(y) = G^5_H(y)$ for $y \in (0, \delta_1)$. Hence,

$$H_6(\nu) = \int_0^{\delta_1} G^6_H(y)dy = \int_0^{\delta_1} \frac{2}{\sigma^2} \exp\left(-\frac{2\beta_1 y}{\sigma^2} \right) dy = \frac{1}{\beta_1} \left[1 - \exp\left(-\frac{2\beta_1 \delta_1}{\sigma^2} \right) \right].$$

Let L^{6-}_t and L^{6+}_t denote the local time of B^6_t at 0 and δ_1, resp. Let $v_6(s) = \inf\{t : L^{6-}_t = s\}$. The random variable $v_6(s)$ is the sum of the lifetimes of excursions of B^6_t from 0 which occur before L^{6-}_t reaches the level s. The last formula and excursion theory give

$$\mathbb{E} v_6(s) = s \frac{1}{\beta_1} \left[1 - \exp\left(-\frac{2\beta_1 \delta_1}{\sigma^2} \right) \right] \overset{\text{df}}{=} s\eta(\delta_1). \tag{3.5}$$

Next we will derive an estimate for $H_6(\nu > t)$. Recall that $Q^z_{-\beta_1}$ denotes the distribution of Brownian motion with drift $-\beta_1$, killed upon hitting 0. Let $\widehat{Q}^z_{-\beta_1}$ denote the distribution of Brownian motion starting from $z \in (0, \delta_1)$, with drift $-\beta_1$, reflected at δ_1, and killed upon hitting 0. It is easy to see that

$$\widehat{Q}^z_{-\beta_1}(\nu > t) \le Q^z_{-\beta_1}(\nu > t),$$

for all $t > 0$ and $z \in (0, \delta_1)$. By Lemma 3.1 (i), Theorem 5.1 (iii) of Burdzy (1987), and scaling,

$$\begin{aligned} H_6(\nu > t) &\le \lim_{z\downarrow 0} \frac{1}{z} \widehat{Q}^z_{-\beta_1}(\nu > t) \\ &\le \lim_{z\downarrow 0} \frac{1}{z} Q^z_{-\beta_1}(\nu > t) = H_5(\nu > t) \le \int_t^\infty \frac{1}{\sigma} (2\pi s^3)^{-1/2} ds. \end{aligned} \tag{3.6}$$

A simple argument based on scaling and the Markov property applied at times $t = k\delta_1^2$, $k = 1, 2, \ldots$, shows that there exists a constant $c_1 > 0$, such that

$$\widehat{Q}^z_{-\beta_1}(\nu > t) \le \exp(-c_1 t\sigma^2/\delta_1^2), \tag{3.7}$$

for all $t > \delta_1^2/\sigma^2$ and $z \in (0, \delta_1)$. Another standard estimate is

$$\widehat{Q}^z_{-\beta_1}(\nu \ge \delta_1^2/\sigma^2) \le zc_2.$$

This combined with the previous estimate gives (with possibly new values for the constants),

$$\widehat{Q}^z_{-\beta_1}(\nu > t) \le zc_2 \exp(-c_1 t\sigma^2/\delta_1^2),$$

for all $t > \delta_1^2/\sigma^2$ and $z \in (0, \delta_1)$. We obtain from this an estimate analogous to (3.6) but applicable for $t > \delta_1^2/\sigma^2$:

$$H_6(\nu > t) \le c_2 \exp(-c_1 t\sigma^2/\delta_1^2). \tag{3.8}$$

Since the excursion process is a Poisson point process, we have from (3.6) and (3.8),

$$\begin{aligned}
\operatorname{Var} v_6(s) &= s\int_0^\infty t^2 H_6(\nu \in dt) \\
&\le s\int_0^{\delta_1^2/\sigma^2} \frac{1}{\sigma} t^2 (2\pi t^3)^{-1/2} dt + s\int_{\delta_1^2/\sigma^2}^\infty \frac{1}{\sigma} (\delta_1^2/\sigma^2)^2 (2\pi t^3)^{-1/2} dt \\
&\quad + s\int_{\delta_1^2/\sigma^2}^\infty t^2 c_2 \frac{\delta_1^2}{c_1\sigma^2} \exp(-c_1 t\sigma^2/\delta_1^2) dt \\
&\le c_3 s\delta_1^3/\sigma^4 + c_4 s\delta_1^3/\sigma^4 + c_5 s\delta_1^8/\sigma^8 \le c_6 s\delta_1^3.
\end{aligned} \tag{3.9}$$

Step 3. We will find a link between processes reflected on sloped lines (in space-time) and within an interval. We will need to define some more variables. First of all, $s_0 > 0$ should be considered a small constant whose value will be chosen later in the proof and which does not change with δ. Recall η defined in (3.5). Let $u_0 > 0$ and $\delta_1 \in (0, \delta)$ be defined by the following two equations $u_0 = (\delta - \delta_1)/(\beta_1 - \beta_2)$, and $s_0 = u_0/\eta(\beta_1, \delta, \sigma^2)$.

Recall that B_t^6 is a reflected Brownian motion in $[0, \delta_1]$ and note that now δ_1 is defined relative to δ. Let B_t^7 be the analogous reflected Brownian motion in $[0, \delta]$.

Note that $\delta - (\beta_1 - \beta_2)t > \delta_1$ for $t \in (0, u_0)$. Hence, on the interval $(0, u_0)$, the upper reflecting boundary for B_t^6 lies below that for B_t^4. This relationship between the upper reflecting boundaries implies that the excursion measure distribution of the lifetime of an excursion from 0 of the process B_t^4 is stochastically larger than that for an excursion of B_t^6, for excursions within the interval $(0, u_0)$. It follows that one can construct B_t^4 and B_t^6 on a common probability space so that $v_6(s) \wedge t \leq v_4(s) \wedge t$ for all $t \leq u_0$, where $v_4(s) = \inf\{t : L_t^{4-} = s\}$. On the other hand, $\delta - (\beta_1 - \beta_2)t < \delta$ for $t > 0$, so the analogous relationship for B^7 goes in the opposite way, i.e., $v_7(s) \wedge t \geq v_4(s) \wedge t$ for all $t \geq 0$.

Although the process B_t^4 starts from 0, by construction, it will be necessary to consider the case when it starts from some other value; in other words, we will now consider a process with the same transition probabilities but a different starting point. The starting point y will be reflected in the notation by writing $\mathbb{P}^y$ or $\mathbb{E}^y$, as usual.

Let T_0^i be the hitting time of 0 for the process B_t^i for $i = 4, 6, 7$. By the previous remarks, we can construct versions of B_t^4 and B_t^7 on the same probability space so that they start from the same point y and $T_0^4 \wedge t \leq T_0^7 \wedge t$ for $t \leq u_0$.

By the strong Markov property applied at T_0^7, we have $\mathbb{E}^y v_7(s) = \mathbb{E}^y T_0^7 + \mathbb{E}^0 v_7(s)$. It follows easily from (3.7), applied to δ rather than δ_1, that

$$\mathbb{E}^y T_0^7 \leq c_7 \delta^2/\sigma^2. \tag{3.10}$$

Consider arbitrarily small $\varepsilon \in (0, 1/4)$. We obtain using (3.5) (applied with δ_1 replaced by δ) and (3.10),

$$\mathbb{E}^y(v_4(s_0)) \leq \mathbb{E}^y(v_7(s_0)) \leq \mathbb{E}^y T_0^7 + \mathbb{E}^0(v_7(s_0)) \leq c_7\delta^2/\sigma^2 + u_0.$$

For small $\delta > 0$, (3.5) shows that $\eta(\delta)$ is approximately $2\delta/\sigma^2$. Hence, $u_0 = s_0\eta(\delta)$ is approximately equal to $2s_0\delta/\sigma^2$. This shows that for small δ, the last displayed inequality yields

$$\mathbb{E}^y(v_4(s_0)) \leq u_0(1 + \varepsilon) = s_0\eta(\delta)(1 + \varepsilon) \leq 2s_0\delta(1 + \varepsilon)^2/\sigma^2. \tag{3.11}$$

Next we will find a lower bound for the same quantity.

By the strong Markov property applied at T_0^6, we have $\mathbb{E}^y v_6(s) = \mathbb{E}^y T_0^6 + \mathbb{E}^0 v_6(s)$ and $\operatorname{Var}(v_6(s) \mid B_0^6 = y) = \operatorname{Var}(T_0^6 \mid B_0^6 = y) + \operatorname{Var}(v_6(s) \mid B_0^6 = 0)$. We have an estimate analogous to (3.10):

$$\mathbb{E}^y T_0^6 \leq c_7 \delta_1^2/\sigma^2, \tag{3.12}$$

and another estimate following from (3.7):

$$\operatorname{Var}(T_0^6 \mid B_0^6 = y) \leq c_8 \delta_1^4/\sigma^4, \tag{3.13}$$

for any $y \in [0, \delta_1]$.

We obtain using (3.5) and (3.12),

$$\mathbb{E}^y(v_6(s_0(1-\varepsilon))) \le \mathbb{E}^y T_0^6 + \mathbb{E}^0(v_6(s_0(1-\varepsilon))) \le c_7\delta_1^2/\sigma^2 + s_0(1-\varepsilon)\eta(\delta_1).$$

For small $\delta > 0$, δ_1 is also small and (3.5) shows that $\eta(\delta_1)$ is about $2\delta_1/\sigma^2$. Hence, $s_0(1-\varepsilon)\eta(\delta_1)$ is approximately equal to $2s_0(1-\varepsilon)\delta_1/\sigma^2$. This shows that for small δ, the last displayed inequality yields

$$\mathbb{E}^y(v_6(s_0(1-\varepsilon))) \le s_0(1-\varepsilon/2)\eta(\delta_1) \le s_0(1-\varepsilon/2)\eta(\delta) = u_0(1-\varepsilon/2). \tag{3.14}$$

A similar estimate for the variance follows from (3.9) and (3.13), for small δ,

$$\mathrm{Var}\,(v_6(s_0(1-\varepsilon)) \mid B_0^6 = y) \le c_8\delta_1^4/\sigma^4 + c_6 s_0(1-\varepsilon)\delta_1^3/\sigma^4 \le c_9 s_0(1-\varepsilon)\delta_1^3/\sigma^4. \tag{3.15}$$

This estimate, (3.14) and the Chebyshev inequality yield,

$$\mathbb{P}^y(v_6(s_0(1-\varepsilon)) \ge u_0) \le \frac{c_9 s_0(1-\varepsilon)\delta_1^3/\sigma^4}{(\varepsilon u_0/2)^2} \le \frac{c_{10}\delta_1^3}{\eta(\delta)\varepsilon^2 u_0\sigma^4} = \frac{c_{10}\delta_1^3}{\eta^2(\delta)\varepsilon^2 s_0\sigma^4}.$$

For small δ we have

$$\delta/\sigma^2 < \eta(\delta) < 4\delta/\sigma^2. \tag{3.16}$$

Hence,

$$\mathbb{P}^y(v_6(s_0(1-\varepsilon)) \ge u_0) \le \frac{c_{11}\delta_1^3}{(\delta/\sigma^2)^2\varepsilon^2 s_0\sigma^4} \le \frac{c_{11}\delta_1}{\varepsilon^2 s_0}. \tag{3.17}$$

We have from (3.14)-(3.17), for small δ,

$$\begin{aligned}\mathbb{E}^y(v_6(s_0(1-\varepsilon)))^2 &= \mathrm{Var}\,(v_6(s_0(1-\varepsilon)) \mid B_0^6 = y) + (\mathbb{E}^y v_6(s_0(1-\varepsilon)))^2 \\ &\le c_9 s_0(1-\varepsilon)\delta_1^3/\sigma^4 + (s_0(1-\varepsilon/2)\eta(\delta))^2 \\ &\le 32 s_0^2(1-\varepsilon/2)^2\delta^2/\sigma^4.\end{aligned}$$

We use this estimate, (3.5) and (3.16)-(3.17) to obtain, for sufficiently small δ,

$$\begin{aligned}\mathbb{E}^y(v_4(s_0)) &\ge \mathbb{E}^y(v_4(s_0) \wedge u_0) \\ &\ge \mathbb{E}^y(v_6(s_0) \wedge u_0) \\ &\ge \mathbb{E}^y(v_6(s_0(1-\varepsilon)) \wedge u_0) \\ &\ge \mathbb{E}^y(v_6(s_0(1-\varepsilon))) - \mathbb{E}^y\left[v_6(s_0(1-\varepsilon))\mathbf{1}_{\{v_6(s_0(1-\varepsilon))\ge u_0\}}\right] \\ &\ge s_0(1-\varepsilon)\eta(\delta_1) - \left(\mathbb{E}^y(v_6(s_0(1-\varepsilon)))^2\mathbb{E}^y(\mathbf{1}_{\{v_6(s_0(1-\varepsilon))\ge u_0\}})^2\right)^{1/2} \\ &= s_0(1-\varepsilon)\eta(\delta_1) - \left(\mathbb{E}^y(v_6(s_0(1-\varepsilon)))^2\mathbb{P}^y(v_6(s_0(1-\varepsilon)) \ge u_0)\right)^{1/2} \\ &\ge 2s_0(1-\varepsilon)^2\delta_1/\sigma^2 - \left(32 s_0^2(1-\varepsilon/2)^2\delta^2/\sigma^4 \cdot \frac{c_{11}\delta_1}{\varepsilon^2 s_0}\right)^{1/2}.\end{aligned} \tag{3.18}$$

It follows from (3.16) and the definition of δ_1 and u_0 that for small $\delta > 0$,

$$\delta_1 = \delta - s_0\eta(\delta)(\beta_1 - \beta_2) \geq \delta(1 - 4s_0(\beta_1 - \beta_2)/\sigma^2).$$

We will choose sufficiently small $s_0 > 0$ (relative to σ, β_1, β_2 and ε) so that $\delta_1 > \delta(1-\varepsilon/2)$. Then the last inequality and (3.18) yield for small δ,

$$\mathbb{E}^y(v_4(s_0)) \geq 2s_0(1-\varepsilon)^3\delta/\sigma^2. \tag{3.19}$$

Step 4. We will apply induction in order to obtain estimates for $\mathbb{E}^0 v_4(js_0)$ with integer $j \geq 1$. At the time $v_4(s_0)$, the distance between the reflecting barriers for B^4_t is equal to $\widetilde{\delta} = \delta - (\beta_1 - \beta_2)v_4(s_0)$, which is less than δ, so we can use the estimates (3.11) and (3.19) with δ replaced by $\widetilde{\delta}$, assuming that δ itself is sufficiently small for the estimates to hold. By the strong Markov property,

$$\mathbb{E}^0(v_4(2s_0) - v_4(s_0) \mid v_4(s_0)) \leq 2\widetilde{\delta}s_0(1+\varepsilon)^2/\sigma^2 = 2[\delta - (\beta_1 - \beta_2)v_4(s_0)]s_0(1+\varepsilon)^2/\sigma^2,$$

and so

$$\begin{aligned}\mathbb{E}^0(v_4(2s_0) - v_4(s_0)) &\leq \mathbb{E}^0 2[\delta - (\beta_1 - \beta_2)v_4(s_0)]s_0(1+\varepsilon)^2/\sigma^2\\ &\leq 2[\delta - (\beta_1 - \beta_2)2\delta s_0(1+\varepsilon)^2/\sigma^2]s_0(1+\varepsilon)^2/\sigma^2\\ &= 2\delta(s_0/\sigma^2)[(1+\varepsilon)^2 - 2(\beta_1 - \beta_2)(s_0/\sigma^2)(1+\varepsilon)^4].\end{aligned}$$

It follows that for small $\delta > 0$,

$$\begin{aligned}\mathbb{E}^0 v_4(2s_0) &= \mathbb{E}^0 v_4(s_0) + \mathbb{E}^0(v_4(2s_0) - v_4(s_0))\\ &\leq 2\delta(s_0/\sigma^2)(1+\varepsilon)^2 + 2\delta(s_0/\sigma^2)[(1+\varepsilon)^2 - 2(\beta_1 - \beta_2)(s_0/\sigma^2)(1+\varepsilon)^4]\\ &= 2\delta(s_0/\sigma^2)[2(1+\varepsilon)^2 - 2(\beta_1 - \beta_2)(s_0/\sigma^2)(1+\varepsilon)^4].\end{aligned}$$

More generally,

$$\begin{aligned}\mathbb{E}^0 v_4((j+1)s_0) &= \mathbb{E}^0 v_4(js_0) + \mathbb{E}^0(v_4((j+1)s_0) - v_4(js_0))\\ &\leq \mathbb{E}^0 v_4(js_0) + 2[\delta - (\beta_1 - \beta_2)\mathbb{E}^0 v_4(js_0)]s_0(1+\varepsilon)^2/\sigma^2\\ &= \mathbb{E}^0 v_4(js_0)[1 - 2(\beta_1 - \beta_2)(s_0/\sigma^2)(1+\varepsilon)^2] + 2\delta(s_0/\sigma^2)(1+\varepsilon)^2.\end{aligned}$$

From this we obtain by induction,

$$\begin{aligned}\mathbb{E}^0 v_4(js_0) &\le \mathbb{E}^0 v_4(s_0)[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^{j-1}\\ &\qquad + 2\delta(s_0/\sigma^2)(1+\varepsilon)^2 \sum_{k=0}^{j-2}[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^k\\ &\le 2\delta(s_0/\sigma^2)(1+\varepsilon)^2[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^{j-1}\\ &\qquad + 2\delta(s_0/\sigma^2)(1+\varepsilon)^2 \sum_{k=0}^{j-2}[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^k\\ &= 2\delta(s_0/\sigma^2)(1+\varepsilon)^2 \frac{1-[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^j}{1-[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]}\\ &= \frac{\delta}{\beta_1-\beta_2}(1-[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^j).\end{aligned}$$

Now fix an arbitrary $a > 0$, an arbitrarily small $\varepsilon > 0$, and choose a sufficiently small small $s_0 > 0$ so that $\delta_1 > \delta(1-\varepsilon/2)$, and such that for some integer j we have $js_0 = a$, and, moreover, j is sufficiently large to imply the following:

$$\begin{aligned}&\frac{\delta}{\beta_1-\beta_2}(1-[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^j)\\ &\qquad = \frac{\delta}{\beta_1-\beta_2}(1-[1-2(\beta_1-\beta_2)(s_0/\sigma^2)(1+\varepsilon)^2]^{a/s_0})\\ &\qquad \le \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)(1+\varepsilon)^3/\sigma^2)).\end{aligned}$$

Then for sufficiently small $\delta > 0$ we have,

$$\mathbb{E}^0 v_4(a) = \mathbb{E}^0 v_4(js_0) \le \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)(1+\varepsilon)^3/\sigma^2)). \tag{3.20}$$

A completely analogous argument using (3.19) in place of (3.11) yields

$$\mathbb{E}^0 v_4(a) \ge \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)(1-\varepsilon)^4/\sigma^2)). \tag{3.21}$$

Since $\varepsilon > 0$ is arbitrarily small, a standard argument based on (3.20)-(3.21) gives for $\delta \downarrow 0$,

$$\mathbb{E}^0 v_4(a) = \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) + o(\delta). \tag{3.22}$$

Step 5. The last part of the proof exploits a relationship between local time and certain stopping times. Recall the local times L_t^{4-} and L_t^{4+}, introduced earlier in the proof. We have for some standard Brownian motion B_t^8,

$$B_t^4 = B_t^8 - \beta_1 t + L_t^{4-} - L_t^{4+}.$$

One has to check that the normalization of the local time, defined relative to the normalization of the excursion laws in (3.1), is the correct one for the above "Lévy formula." This can be done, for example, by comparing our normalizations with those in Theorems 3.6.17 and 6.2.23 in Karatzas and Shreve (1988).

Note that the σ-fields generated by B^4_t and B^8_t are identical so $v_4(a)$ is a stopping time for B^8_t. We have $B^4_{v_4(a)} = 0$ and $L^{4-}_{v_4(a)} = a$, so

$$0 = B^8_{v_4(a)} - \beta_1 v_4(a) + a - L^{4+}_{v_4(a)}. \tag{3.23}$$

Since $v_4(a)$ is bounded by $\delta/(\beta_1 - \beta_2)$ the optional stopping theorem yields $\mathbb{E}B^8_{v_4(a)} = 0$, and so, using (3.22),

$$\mathbb{E}L^{4+}_{v_4(a)} = a - \mathbb{E}\beta_1 v_4(a) = a - \delta\frac{\beta_1}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)) + o(\delta). \tag{3.24}$$

Now recall that $L^{4+}_{v_4(a)}$ has the same distribution as $L^{x+\delta}_\infty$ given $\{L^x_\infty = a\}$. This observation and the last formula complete the proof of part (i) of the lemma.

(ii) The proof of part (ii) of the lemma uses a formula analogous to (3.24), but requires some additional work.

Recall that δ was positive in part (i) of the proof; it will be negative in the present part.

Recall the transformations of B_t from the proof of (i). It is easy to see that analogous transformations in the current case do not lead to B^4_t which is a Brownian motion starting from 0, with drift $-\beta_1$, reflected on the horizontal axis and the line $t \to \delta - (\beta_1 - \beta_2)t$ (with $\delta > 0$), but instead they give a Brownian motion $\widetilde{B}^4_t$ starting from 0, with drift $-\beta_2$, reflected on the horizontal axis and the line $t \to \delta + (\beta_1 - \beta_2)t$ (with $\delta < 0$).

A subtle but significant difference from (i) is that the infinite excursion of B_t from the graph of X^x_t will go in the direction of the graph of $X^{x+\delta}_t$ and so it will generate some more local time. By Lemma 3.1 (i) and Remark 3.2 (ii), the excursions with finite lifetimes have the same intensities for Brownian motions with drifts β_2 and $-\beta_2$, so we can use estimate (3.24) for the portion of the local time generated before the last, infinite excursion of B_t from the graph of X^x_t. The estimate has to be modified as β_1 has to be replaced by β_2, and so we obtain

$$a - |\delta|\frac{\beta_2}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)) + o(\delta). \tag{3.25}$$

To this we will have to add the local time spent by B_t on the graph of $X^{x+\delta}_t$ during its final, infinite excursion from the graph of X^x_t. The rest of the proof is devoted to that calculation.

Let U be the first time when the final, infinite excursion of B_t from the graph of X_t^x hits the graph of $X_t^{x+\delta}$. Let $\delta_1 = |X_U^x - X_U^{x+\delta}|$. First, we will condition on δ_1. The process $\{B_t, t \geq U\}$ is a Brownian motion conditioned not to hit the line $t \to B_U + \delta_1 + \beta_2 t$. By subtracting the drift and flipping the process to the other side of the horizontal axis, we may consider a Brownian motion B_t^9 starting from δ_1, with drift β_2, conditioned not to hit 0. We will estimate the amount of the local time this process spends on the graph of a solution Y_t to (1.1) with β_2 replaced by $-(\beta_1 - \beta_2)$, β_1 replaced by 0, and B_t replaced by B_t^9.

Let H^{δ_1} be the excursion law for excursions above the level δ_1 for Brownian motion with drift β_2, conditioned not to hit 0. Let F_∞ denote the set of excursions with infinite lifetime. We will compute $H^{\delta_1}(F_\infty)$. Let $Q_{\beta_2}^z$ be the distribution of Brownian motion with drift β_2. Then

$$\begin{aligned} H^{\delta_1}(F_\infty) &= \lim_{z \downarrow 0} \frac{1}{z} \cdot Q_{\beta_2}^{\delta_1+z}(T_\infty < T_{\delta_1} \mid T_\infty < T_0) \\ &= \lim_{z \downarrow 0} \frac{1}{z} \cdot \frac{Q_{\beta_2}^{\delta_1+z}(T_\infty < T_{\delta_1} \text{ and } T_\infty < T_0)}{Q_{\beta_2}^{\delta_1+z}(T_\infty < T_0)} \\ &= \lim_{z \downarrow 0} \frac{1}{z} \cdot \frac{Q_{\beta_2}^{\delta_1+z}(T_\infty < T_{\delta_1})}{Q_{\beta_2}^{\delta_1+z}(T_\infty < T_0)}. \end{aligned}$$

Recall that the scale function $S(y)$ for Brownian motion with drift β_2 is equal to $\exp(-2\beta_2 y/\sigma^2)$. This gives

$$\begin{aligned} H^{\delta_1}(F_\infty) &= \lim_{z \downarrow 0} \frac{1}{z} \cdot \frac{S(\delta_1 + z) - S(\delta_1)}{S(\infty) - S(\delta_1)} \cdot \frac{S(\infty) - S(0)}{S(\delta_1 + z) - S(0)} \\ &= \lim_{z \downarrow 0} \frac{1}{z} \cdot \frac{\exp(-2\beta_2(\delta_1 + z)/\sigma^2) - \exp(-2\beta_2\delta_1/\sigma^2)}{0 - \exp(-2\beta_2\delta_1/\sigma^2)} \cdot \frac{0 - 1}{\exp(-2\beta_2(\delta_1 + z)/\sigma^2) - 1} \\ &= \frac{2\beta_2}{\sigma^2[1 - \exp(-2\beta_2\delta_1/\sigma^2)]}. \end{aligned}$$

If we fix arbitrarily small $\varepsilon > 0$ then for sufficiently small $\delta_1 > 0$ we have

$$\frac{1}{\delta_1} \leq H^{\delta_1}(F_\infty) \leq (1 + \varepsilon)\frac{1}{\delta_1}. \tag{3.26}$$

We proceed to calculate the expected time to hit δ_1 for Brownian motion with drift β_2, starting from $\delta_1 - z$ and conditioned not to hit 0, where $z \in (0, \delta_1)$. If we take

$$s(z) = \exp\left[-\int_0^z 2\beta_2/\sigma^2 dy\right] = \exp(-2\beta_2 z/\sigma^2),$$

and

$$S(z) = \int_0^z s(y)dy = \frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2 z/\sigma^2)],$$

then formula (9.9) on p. 264 of Karlin and Taylor (1981) yields

$$\begin{aligned}
&\mathbb{E}^{\delta_1 - z}(T_{\delta_1} \mid T_{\delta_1} < T_0) \\
&= \frac{2[S(\delta_1) - S(\delta_1 - z)]}{S(\delta_1)S(\delta_1 - z)} \int_0^{\delta_1 - z} \frac{S^2(y)}{\sigma^2 s(y)} dy + 2\int_{\delta_1 - z}^{\delta_1} \frac{S(y)[S(\delta_1) - S(y)]}{\sigma^2 s(y) S(\delta_1)} dy \\
&= \frac{2\left[\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2\delta_1/\sigma^2)] - \frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2(\delta_1 - z)/\sigma^2)]\right]}{\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2\delta_1/\sigma^2)]\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2(\delta_1 - z)/\sigma^2)]} \times \\
&\qquad \int_0^{\delta_1 - z} \frac{\frac{\sigma^4}{4{\beta_2}^2}[1 - \exp(-2\beta_2 y/\sigma^2)]^2}{\sigma^2 \exp(-2\beta_2 y/\sigma^2)} dy \\
&\quad + 2\int_{\delta_1 - z}^{\delta_1} \left(\frac{\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2 y/\sigma^2)]}{\sigma^2 \exp(-2\beta_2 y/\sigma^2)\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2\delta_1/\sigma^2)]} \times \right. \\
&\qquad \left. \left[\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2\delta_1/\sigma^2)] - \frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2 y/\sigma^2)]\right] \right) dy \\
&= \frac{2[\exp(-2\beta_2(\delta_1 - z)/\sigma^2) - \exp(-2\beta_2\delta_1/\sigma^2)]}{\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2\delta_1/\sigma^2)][1 - \exp(-2\beta_2(\delta_1 - z)/\sigma^2)]} \times \\
&\qquad \int_0^{\delta_1 - z} \frac{\frac{\sigma^4}{4{\beta_2}^2}[1 - \exp(-2\beta_2 y/\sigma^2)]^2}{\sigma^2 \exp(-2\beta_2 y/\sigma^2)} dy \\
&\quad + 2\int_{\delta_1 - z}^{\delta_1} \frac{\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2 y/\sigma^2)][\exp(-2\beta_2 y/\sigma^2) - \exp(-2\beta_2\delta_1/\sigma^2)]}{\sigma^2 \exp(-2\beta_2 y/\sigma^2)[1 - \exp(-2\beta_2\delta_1/\sigma^2)]} dy.
\end{aligned}$$

The expected lifetime of an excursion below δ_1 for the Brownian motion with drift β_2, starting from δ_1 and conditioned not to hit 0 is therefore equal to

$$\begin{aligned}
&\lim_{z \downarrow 0} \frac{1}{z} \mathbb{E}^{\delta_1 - z}(T_{\delta_1} \mid T_{\delta_1} < T_0) \\
&\quad = \frac{2\frac{2\beta_2}{\sigma^2}\exp(-2\beta_2\delta_1/\sigma^2)}{\frac{\sigma^2}{2\beta_2}[1 - \exp(-2\beta_2\delta_1/\sigma^2)][1 - \exp(-2\beta_2\delta_1/\sigma^2)]} \int_0^{\delta_1} \frac{\frac{\sigma^4}{4{\beta_2}^2}[1 - \exp(-2\beta_2 y/\sigma^2)]^2}{\sigma^2 \exp(-2\beta_2 y/\sigma^2)} dy \\
&\quad \le c_1\delta_1, \qquad (3.27)
\end{aligned}$$

for small $\delta_1 > 0$ and some c_1 depending on β_2 and σ^2 but not on δ_1.

Fix arbitrarily small $\varepsilon > 0$. We are ready to derive estimates for the total amount of local time, say L_∞^{9+}, that B_t^9 spends on the graph of Y_t.

On one hand, the estimate (3.26) shows that L_∞^{9+} is stochastically bounded by an exponential random variable with mean δ_1, for sufficiently small $\delta_1 > 0$.

Let $v_9^+(a)$ be the time spent by B_t^9 between Y_t and the horizontal axis before the time when L_t^{9+} hits a. Since Y_t is non-increasing, the estimate (3.27) can be used as an upper bound for the expected duration of an excursion below Y_t, for every $t \geq 0$. Fix arbitrarily large $b < \infty$ and arbitrarily small $\varepsilon > 0$. We have from excursion theory,

$$\mathbb{E} v_9^+(b\delta_1) \leq b\delta_1 c_1 \delta_1,$$

and so, for sufficiently small $\delta_1 > 0$,

$$\mathbb{P}(v_9^+(b\delta_1) \geq \delta_1\varepsilon) \leq \frac{bc_1{\delta_1}^2}{\delta_1\varepsilon} = \frac{bc_1}{\varepsilon}\delta_1 < \varepsilon.$$

We see that with probability greater than $1-\varepsilon$, the distance between Y_t and the horizontal axis remains greater than $\delta_1 - \delta_1\varepsilon(\beta_1 - \beta_2)$, at least until the time when L_t^{9+} exceeds $b\delta_1$. On this time interval and given this event, the intensity for the arrival process of the infinite excursion is bounded above by $(1+\varepsilon)/(\delta_1(1-\varepsilon))$, by (3.26). Hence, $\mathbb{E}L_\infty^{9+}/\delta_1$ can be made arbitrarily close to 1, by choosing large b, then small ε and finally small $|\delta| > 0$ (note that $\delta_1 \leq |\delta|$).

Finally, in order to obtain an unconditioned estimate for $\mathbb{E}L_\infty^{9+}$, we have to average over the possible values of δ_1. Let $\widetilde{v}_4(a)$ be the time when the local time of $\widetilde{B}_t^4$ (defined earlier in the proof of part (ii)) reaches a. The same argument which gives (3.22) yields the following estimate,

$$\begin{aligned}
\mathbb{E}L_\infty^{9+} &= \mathbb{E}\delta_1 + o(\delta) \\
&= |\delta| - \mathbb{E}(\beta_1 - \beta_2)\widetilde{v}_4(a) + o(\delta) \\
&= |\delta| - |\delta|\frac{\beta_1 - \beta_2}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)) + o(\delta) \\
&= |\delta|\exp(-2a(\beta_1 - \beta_2)/\sigma^2)) + o(\delta).
\end{aligned}$$

Adding this quantity to (3.25) gives the formula in Lemma 3.4 (ii). □

Lemma 3.5. *Fix $x, a, \beta_1, \beta_2 > 0$ and assume that $\beta_1 - \beta_2 > 0$. Then*

$$\operatorname{Var}(L_\infty^{x+\delta} \mid L_\infty^x = a) = \frac{\delta}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)) + o(\delta),$$

for $\delta \downarrow 0$. The same formula holds if $x < 0$ and $\delta \uparrow 0$.

Proof. First suppose that $x, \delta > 0$ and recall the notation and definitions from the proof of Lemma 3.4 (i). It follows from (3.23) that

$$L_{v_4(a)}^{4+} - a = B_{v_4(a)}^8 - \beta_1 v_4(a).$$

We have using (3.22),

$$\begin{aligned}\mathbb{E}(L^{4+}_{v_4(a)}-a)^2 &= \mathbb{E}(B^8_{v_4(a)}-\beta_1 v_4(a))^2 \qquad (3.28)\\ &= \mathbb{E}(B^8_{v_4(a)})^2 - 2\beta_1\mathbb{E}\left[B^8_{v_4(a)}v_4(a)\right] + \mathbb{E}(v_4(a))^2\\ &= \mathbb{E}v_4(a) - 2\beta_1\mathbb{E}\left[B^8_{v_4(a)}v_4(a)\right] + \mathbb{E}(v_4(a))^2\\ &= \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) + o(\delta) - 2\beta_1\mathbb{E}\left[B^8_{v_4(a)}v_4(a)\right] + \mathbb{E}(v_4(a))^2.\end{aligned}$$

Recall that $v_4(a)$ is bounded by $\delta/(\beta_1-\beta_2)$. Hence,

$$\mathbb{E}(v_4(a))^2 \le \delta^2/(\beta_1-\beta_2)^2, \qquad (3.29)$$

and

$$\begin{aligned}\mathbb{E}B^8_{v_4(a)}v_4(a) &\le \left(\mathbb{E}(B^8_{v_4(a)})^2\mathbb{E}(v_4(a))^2\right)^{1/2} \qquad (3.30)\\ &= \left(\mathbb{E}v_4(a)\mathbb{E}(v_4(a))^2\right)^{1/2}\\ &\le \left(\left[\frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) + o(\delta)\right]\cdot\delta^2/(\beta_1-\beta_2)^2\right)^{1/2}\\ &= o(\delta).\end{aligned}$$

Combining (3.28)-(3.30) yields

$$\mathbb{E}(L^{4+}_{v_4(a)}-a)^2 = \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) + o(\delta).$$

This implies

$$\begin{aligned}\operatorname{Var} L^{4+}_{v_4(a)} &= \mathbb{E}(L^{4+}_{v_4(a)} - \mathbb{E}L^{4+}_{v_4(a)})^2\\ &= \mathbb{E}(L^{4+}_{v_4(a)}-a)^2 - (\mathbb{E}L^{4+}_{v_4(a)}-a)^2\\ &= \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) + o(\delta)\\ &\qquad - \left[\delta\frac{\beta_1}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) + o(\delta)\right]^2\\ &= \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) + o(\delta).\end{aligned}$$

Similarly to the proof of Lemma 3.4 (i), we have $\operatorname{Var}(L^{x+\delta}_\infty \mid L^x_\infty = a) = \operatorname{Var} L^{4+}_{v_4(a)}$, which combined with the last formula proves the lemma in the case $x > 0$.

Now consider the case $x, \delta < 0$. We argue as in the proof of Lemma 3.4 (ii) that we have to add a contribution from the local time on $X_t^{x+\delta}$ generated by the infinite excursion of B_t below X_t^x. We have shown in the proof of Lemma 3.4 (ii) that the local time on $X_t^{x+\delta}$ generated by the infinite excursion is stochastically bounded by an exponential random variable with mean δ so its variance is bounded by $2\delta^2$, and, therefore, the contribution to the variance from the infinite excursion is negligible. The same formula holds in the case $x < 0$ as in the case $x > 0$. $\square$

Recall that L_t^x denotes the local time of $B_t - X_t^x$ at 0. The following result is analogous to Trotter's theorem on the joint continuity of local times for Brownian motion (see Karatzas and Shreve (1988) or Knight (1981)).

Theorem 3.6. *Assume that $\beta_1, \beta_2 > 0$ and $\beta_1 - \beta_2 > 0$. There exists a version of the process $(x,t) \to L_t^x$ which is jointly continuous in both variables.*

Proof. Note that X_t^x and X_t^y increase at the same rate when B_t does not lie between X_t^x and X_t^y, and by the assumptions on β_1 and β_2, they grow closer together when B_t does lie between them. Therefore, for all x, y and $t \geq 0$,

$$|X_t^x - X_t^y| \leq |x - y|. \tag{3.31}$$

Define $G(x) = \mathbb{E}L_\infty^x$. The excursion law for Brownian motion below the line $t \to \beta_2 t$ gives mass $2\beta_2/\sigma^2$ to excursions with infinite lifetime, by Lemma 3.1 (iii). By excursion theory, the waiting time (in terms of local time) for the first excursion with infinite lifetime is exponential with mean $\sigma^2/(2\beta_2)$. This says that the distribution of L_∞^0 is exponential with mean $\sigma^2/(2\beta_2)$. This and the strong Markov property applied at the first time when B_t intersects X_t^x imply that for some $c_1 < \infty$ and all x, we have $G(x) \leq c_1$. An easy conditioning argument that combines this observation with Lemma 3.4 shows that for all x and y,

$$|G(x) - G(y)| \leq c_2 |x - y|. \tag{3.32}$$

The process (X_t^x, B_t) is strong Markov, and L_t^x is an additive functional. So by the Markov property,

$$\begin{aligned} \mathbb{E}[L_\infty^x - L_t^x \mid \mathcal{F}_t] &= \mathbb{E}[L_\infty^x \circ \theta_t \mid \mathcal{F}_t] \\ &= G(X_t^x - B_t). \end{aligned}$$

Therefore

$$\mathbb{E}[L_\infty^x - L_t^x \mid \mathcal{F}_t] \le c_1.$$

Also, using (3.31) and (3.32),

$$\begin{aligned}|\mathbb{E}[(L_\infty^x - L_\infty^y) - (L_t^x - L_t^y) \mid \mathcal{F}_t]| &= |G(X_t^x - B_t) - G(X_t^y - B_t)| \\ &\le c_2|X_t^x - X_t^y| \\ &\le c_2|x-y|.\end{aligned}$$

By Bass (1995), Proposition I.6.14,

$$\mathbb{E}[\sup_t |L_t^x - L_t^y|^4] \le c_4|x-y|^2. \tag{3.33}$$

By Kolmogorov's criterion and standard arguments (cf. the proof of Proposition I.6.16 of Bass (1995)), we deduce that there exists a version of L_t^x that is jointly continuous in x and t. □

A classical Ray-Knight theorem (see Knight (1981), Revuz and Yor (1991) or Yor (1997)) asserts, roughly speaking, that if L_t^x is the local time for the standard Brownian motion then $x \to L_T^x$ is a diffusion for certain stopping times T. As a part of that theorem, the infinitesimal parameters of the diffusion are also given. We prove a similar result for our family of local times, with $T \equiv \infty$. Recall that we assume that $B_0 = 0$.

Theorem 3.7. *Suppose that $\beta_1, \beta_2 > 0$ and $\beta_1 - \beta_2 > 0$. The distribution of L_∞^0 is exponential with mean $\sigma^2/(2\beta_2)$. The process $\{L_\infty^x, x \ge 0\}$ is a diffusion with the infinitesimal drift*

$$\widetilde{\mu}(a) = -\frac{\beta_1}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)),$$

and infinitesimal variance

$$\widetilde{\sigma}^2(a) = \frac{1}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)).$$

The process $\{L_\infty^{-x}, x \ge 0\}$ is a diffusion with the infinitesimal drift

$$\widehat{\mu}(a) = -\frac{\beta_2}{\beta_1 - \beta_2} + \frac{\beta_1}{\beta_1 - \beta_2}\exp(-2a(\beta_1 - \beta_2)/\sigma^2),$$

and the same infinitesimal variance

$$\widetilde{\sigma}^2(a) = \frac{1}{\beta_1 - \beta_2}(1 - \exp(-2a(\beta_1 - \beta_2)/\sigma^2)).$$

Proof. We have already shown in the proof of Theorem 3.6 that the distribution of L^0_∞ is exponential with mean $\sigma^2/(2\beta_2)$.

The Markovian character of the process $\{L^x_\infty, x \geq 0\}$ at any fixed "time" $x = y$ follows from the independence of the Poisson processes of excursions of B_t below and above X^y_t. The same remark applies to $\{L^{-x}_\infty, x \geq 0\}$. The infinitesimal parameters of the processes were calculated in Lemmas 3.2 and 3.3.

The process $x \to L^x_\infty$ is continuous, by Theorem 3.6. Since its infinitesimal drift is bounded and the infinitesimal variance is nondegenerate, there is a unique (in law) Markov process with this infinitesimal drift and variance (cf. Bass (1997), Section IV.3), and this Markov process is in fact a strong Markov process. $\square$

Theorem 3.8. *Suppose* $\beta_1, \beta_2 > 0$ *and* $\beta_1 - \beta_2 > 0$. *For fixed* $t > 0$, *we have a.s., for all* $x, x_1, x_2 \in \mathbb{R}$,

$$\left.\frac{d}{dy} X^y_t\right|_{y=x} = \exp(-2L^x_t(\beta_1 - \beta_2)/\sigma^2),$$

and

$$X^{x_2}_t - X^{x_1}_t = \int_{x_1}^{x_2} \exp(-2L^x_t(\beta_1 - \beta_2)/\sigma^2) dx.$$

Proof. First we will prove an estimate analogous to (3.22) except that it will hold for $v_4(a)$ itself rather than its expectation. Recall the notation and definitions from the proof of Lemma 3.4 (i).

The following estimate is completely analogous to (3.17) except that we state it for the process B^7_t rather than B^6_t, so δ_1 is replaced by δ in the bound.

$$\mathbb{P}^y(v_7(s_0(1-\varepsilon)) \geq u_0) \leq \frac{c_{11}\delta}{\varepsilon^2 s_0 \sigma^2}.$$

We can further modify the estimate by replacing $s_0(1-\varepsilon)$ with s_0, so that

$$\mathbb{P}^y(v_7(s_0) \geq u_0/(1-\varepsilon)) \leq \frac{c_{11}\delta(1-\varepsilon)}{\varepsilon^2 s_0 \sigma^2}.$$

This and (3.16) imply that for small ε and δ we have

$$v_7(s_0) \leq u_0/(1-\varepsilon) \leq 2s_0\delta(1+\varepsilon)^2/\sigma^2 \tag{3.34}$$

with probability greater than or equal to $1 - c_{11}\delta(1-\varepsilon)/(\varepsilon^2 s_0\sigma^2)$. The inequality (3.34) is analogous to (3.11) and can be used in the same way as in the argument between (3.19) and (3.20) to prove a formula analogous to (3.20):

$$v_4^\delta(a) = v_4(js_0) \leq \frac{\delta}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)(1+\varepsilon)^3/\sigma^2)), \tag{3.35}$$

where δ in $v_4^\delta(a)$ indicates the dependence of $v_4^\delta(a)$ on δ. The above argument requires that we can use an estimate analogous to (3.34) at every stage of the inductive procedure, i.e., at every stopping time $v_4(ms_0)$ for $m = 1, 2, \ldots, j-1$. All of these estimates hold simultaneously with probability greater than

$$1 - (j-1)c_{11}\delta(1-\varepsilon)/(\varepsilon^2 s_0\sigma^2).$$

This shows that the probability that (3.35) fails to hold is smaller than

$$(j-1)c_{11}\delta(1-\varepsilon)/(\varepsilon^2 s_0\sigma^2).$$

Now fix arbitrarily small $\varepsilon_1 > 0$ and let $\delta_k = (1-\varepsilon_1)^k$. Let A_k be the event in (3.35) with δ replaced by δ_k, i.e.,

$$A_k = \left\{ v_4^{\delta_k}(a) \leq \frac{\delta_k}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)(1+\varepsilon)^3/\sigma^2)) \right\}.$$

We have

$$\sum_{k=0}^\infty (j-1)c_{11}\delta_k(1-\varepsilon)/(\varepsilon^2 s_0\sigma^2) = \sum_{k=0}^\infty (j-1)c_{11}(1-\varepsilon_1)^k(1-\varepsilon)/(\varepsilon^2 s_0\sigma^2) < \infty,$$

so only a finite number of events A_k may fail to hold. Consider an ω and k_0 such that all events $A_k, k \geq k_0$, hold for this ω. Suppose that $\delta \in (0, \delta_{k_0})$. Then $\delta \in [\delta_{k_1-1}, \delta_{k_1}]$ for some $k_1 \geq k_0$. Since A_{k_1} holds, we have

$$\begin{aligned} v_4^\delta(a) \leq v_4^{\delta_{k_1}}(a) &\leq \frac{\delta_{k_1}}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)(1+\varepsilon)^3/\sigma^2)) \\ &\leq \frac{\delta/(1-\varepsilon_1)}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)(1+\varepsilon)^3/\sigma^2)). \end{aligned}$$

This inequality holds with probability one for all sufficiently small $\delta > 0$. Since $\varepsilon > 0$ and $\varepsilon_1 > 0$ are arbitrarily small, we see that a.s.,

$$\limsup_{\delta\to 0+} \frac{v_4^\delta(a)}{\delta} \le \frac{1}{\beta_1-\beta_2}(1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)).$$

The same lower bound can be obtained for liminf in a completely analogous way, so with probability one,

$$\lim_{\delta\to 0+} \frac{v_4^\delta(a)}{\delta} = \frac{1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)}{\beta_1-\beta_2}. \tag{3.36}$$

Suppose $a > 0$ and let $v(a) = \inf\{t \ge 0 : L_t^x = a\}$. Fix some $x \in \mathbb{R}$ and consider $\delta > 0$. We will first find the right hand side derivative $\frac{d^+}{dy} X^y_{v(a)}\Big|_{y=x}$. Let $T = \inf\{t : B_t = X_t^x\}$ and let U_1 be the amount of time spent by B_t between the graphs of X_t^x and $X_t^{x+\delta}$ on the time interval $[0,T]$. We will write U_2 to denote the amount of time spent by B_t between the graphs of X_t^x and $X_t^{x+\delta}$, between times T and $v(a)$.

If $x \ge 0$ then $U_1 = 0$. If $x < 0$ then U_1 is not greater than the amount of time U_3 spent by B_t between the lines $t \to x + \beta_1 t$ and $t \to x + \delta + \beta_1 t$, until the hitting time T. Standard arguments show that for any arbitrarily small $\varepsilon > 0$, we have $U_3/\delta^{2-\varepsilon} \to 0$ as $\delta \to 0$, a.s. Note that the distance between $X_t^{x+\delta}$ and X_t^x decreases by $(\beta_1-\beta_2)u$ on any interval where the Brownian motion B_t spends u units between these functions. Hence,

$$X^{x+\delta}_{v(a)} - X^x_{v(a)} = \delta - (\beta_1-\beta_2)(U_1+U_2).$$

The random variable U_2 may be identified with $v_4^\delta(a)$, so (3.36) gives for any fixed a, a.s.,

$$\begin{aligned}
\frac{d^+}{dy} X^y_{v(a)}\Big|_{y=x} &= \lim_{\delta\to 0} \frac{X^{x+\delta}_{v(a)} - X^x_{v(a)}}{\delta} \\
&= \lim_{\delta\to 0} \frac{\delta - (\beta_1-\beta_2)(U_1+U_2)}{\delta} \\
&= 1 - \lim_{\delta\to 0} \frac{(\beta_1-\beta_2)U_1}{\delta} - \lim_{\delta\to 0} \frac{(\beta_1-\beta_2)v_4^\delta(a)}{\delta} \\
&= 1 - 0 - (1-\exp(-2a(\beta_1-\beta_2)/\sigma^2)) \\
&= \exp(-2L^x_{v(a)}(\beta_1-\beta_2)/\sigma^2).
\end{aligned}$$

The above holds simultaneously for all rational a, with probability one. Since $t \to L_t^x$ and $t \to X_t^y - X_t^z$ are continuous monotone functions, an elementary argument can be used to extend the last formula to fixed times, i.e.,

$$\frac{d^+}{dy} X_t^y\Big|_{y=x} = \exp(-2L_t^x(\beta_1-\beta_2)/\sigma^2), \tag{3.37}$$

simultaneously for all $t \geq 0$, a.s.

Fix some $t > 0$. By Fubini's theorem, (3.37) holds for almost all x, a.s. We have $|X_t^y - X_t^z| \leq |y - z|$ for all y and z. Since the function $y \to X_t^y$ is Lipschitz, it has a derivative almost everywhere and so for a fixed t, we may replace the right hand derivative with the usual derivative in (3.37), for almost all x. The function $x \to L_t^x$ is continuous, so the derivative in (3.37) is equal almost everywhere to a continuous function. This implies that the derivative is equal to the function everywhere. This proves the first assertion of the theorem. The second one follows from the first one and from the Lipschitz character of $y \to X_t^y$. □

Remark 3.9. Suppose that X_t^y are solutions to (1.1) and assume that $\beta_1, \beta_2 > 0$ and $\beta_1 - \beta_2 > 0$. Fix some $t > 0$ and consider the function $y \to X_t^y$. We will sketch an argument showing that $y \to X_t^y$ is $C^{1+\gamma}$ for every $\gamma < 1/2$, i.e., that the function has a derivative which is Hölder continuous with Hölder exponent γ.

Fix any $z \in \mathbb{R}$. With probability 1, $B_t \neq X_t^z$, and with strictly positive probability, there exists $\varepsilon > 0$ such that $B_s \neq X_s^y$ for all $y \in (z - \varepsilon, z + \varepsilon)$ and $s \geq t$. It follows that if a local property holds for the function $y \to L_\infty^y$ with probability 1, it must hold for $y \to L_t^y$, with probability 1. Since $y \to L_\infty^y$ is a diffusion, its paths are Hölder continuous with exponent γ for every $\gamma < 1/2$. It follows that the same is true of $y \to L_t^y$. Theorem 3.8 now implies that $y \to X_t^y$ is $C^{1+\gamma}$ for every $\gamma < 1/2$. The same argument shows that $y \to X_t^y$ is not $C^{3/2}$.

4. Time and direction of bifurcation. We will first address the question of the direction of bifurcation for the equation (1.3). We will say that a positive bifurcation occurs if for some t_1 we have $X_t > B_t$ for all $t > t_1$. The definition of a negative bifurcation is analogous. If β_1 and β_2 have the same sign then it is easy to see that a bifurcation will occur with probability one and its direction will be the same as the sign of β_k's. If $\beta_1 > 0$ and $\beta_2 < 0$ then there will be no bifurcation. The next theorem deals with the only remaining, non-trivial case.

Theorem 4.1. *Consider the equation (1.3) with $t_0 = x_0 = 0$. Assume that $\beta_1 < 0$ and $\beta_2 > 0$. Let*

$$\lambda_j = \frac{2|\beta_j|^{1/(\alpha_j+1)}(\alpha_j + 1)^{\alpha_j/(\alpha_j+1)}}{\sigma^{2/(\alpha_j+1)}\Gamma(1/(\alpha_j + 1))},$$

for $j = 1, 2$. The probability of a negative bifurcation is equal to $\lambda_1/(\lambda_1 + \lambda_2)$. When $\alpha_1 = \alpha_2 = 0$, the formula simplifies to $|\beta_1|/(|\beta_1| + |\beta_2|)$.

Before proving Theorem 4.1 we present a lemma which may have some interest of its own.

Lemma 4.2. *Assume that $\beta_1 < 0$ and $\beta_2 > 0$. Consider a solution X_t to (1.3) with $t_0 = x_0 = 0$. There exists $\gamma > 0$, depending on $\alpha_1, \alpha_2, \beta_1, \beta_2$, such that $X_t/t^{1/2+\gamma}$ converges in probability to 0 as $t \to 0$.*

Proof. Let us assume that $-1 < \alpha_1 \le 0 \le \alpha_2$. The other cases may be treated in a similar way. Let $U = \sup\{s \le t : X_s - B_s \ge -t^{1/2}\}$. For $s \in (U, t)$ we have $X_s - B_s < -t^{1/2}$ so for such s, $|dX_s/ds| \le \beta_1 t^{(1/2)\alpha_1}$. It follows that

$$|X_t - X_U| \le -(t-U)\beta_1 t^{(1/2)\alpha_1} \le -\beta_1 t^{1+(1/2)\alpha_1},$$

and so

$$\begin{aligned} B_t - X_t &\le (B_t - B_U) + (B_U - X_U) + (X_U - X_t) \\ &\le \left(\max_{s\in(0,t)} B_s - \min_{s\in(0,t)} B_s \right) + t^{1/2} - \beta_1 t^{1+(1/2)\alpha_1}. \end{aligned}$$

This implies that

$$\begin{aligned} &\mathbb{E}|B_t - X_t|^{\alpha_1} \mathbf{1}_{\{B_t - X_t > 0\}} \\ &\le \mathbb{E}\left| \left(\max_{s\in(0,t)} B_s - \min_{s\in(0,t)} B_s \right) + t^{1/2} - \beta_1 t^{1+(1/2)\alpha_1} \right|^{\alpha_1} \\ &\le 3^{\alpha_1} \left[\mathbb{E}\left(\max_{s\in(0,t)} B_s - \min_{s\in(0,t)} B_s \right)^{\alpha_1} + t^{(1/2)\alpha_1} + |\beta_1|^{\alpha_1} t^{\alpha_1 + (1/2)\alpha_1^2} \right] \\ &\le c_1 t^{(1/2)\alpha_1} + c_2 |\beta_1|^{\alpha_1} t^{\alpha_1 + (1/2)\alpha_1^2}. \end{aligned}$$

Recall from (2.2) that

$$X_t = \int_0^t \left[\beta_1 |X_s - B_s|^{\alpha_1} \mathbf{1}_{\{X_s - B_s \le 0\}} + \beta_2 |X_s - B_s|^{\alpha_2} \mathbf{1}_{\{X_s - B_s > 0\}} \right] ds.$$

From this we have the following estimate

$$\begin{aligned} \mathbb{E}X_t &\ge \mathbb{E}\int_0^t \beta_1 |X_s - B_s|^{\alpha_1} \mathbf{1}_{\{X_s - B_s \le 0\}} ds \\ &= \int_0^t \mathbb{E}(\beta_1 |X_s - B_s|^{\alpha_1} \mathbf{1}_{\{X_s - B_s \le 0\}}) ds \\ &\ge \beta_1 \int_0^t (c_1 s^{(1/2)\alpha_1} + c_2 |\beta_1|^{\alpha_1} s^{\alpha_1 + (1/2)\alpha_1^2}) ds \\ &= \beta_1 \left(c_3 t^{1+(1/2)\alpha_1} + c_4 |\beta_1|^{\alpha_1} t^{1+\alpha_1+(1/2)\alpha_1^2} \right). \end{aligned}$$

Since $\alpha_1 > -1$, the exponents $1 + (1/2)\alpha_1$ and $1 + \alpha_1 + (1/2)\alpha_1^2$ are greater than $1/2$ and so for some $\gamma > 0$ and every $c_5 > 0$, $\liminf_{t \to 0} c_5 \mathbb{E} X_t / t^{1/2+\gamma} \geq 0$. It follows that

$$\lim_{t \to 0} \mathbb{P}(X_t / t^{1/2+\gamma} < -c_6) = 0, \tag{4.1}$$

for every $c_6 > 0$.

Recall that $\alpha_2 \geq 0$. Since

$$X_t \leq \int_0^t \beta_2 |X_s - B_s|^{\alpha_2} \mathbf{1}_{\{X_s - B_s > 0\}} ds,$$

an elementary argument shows that for small t we have $X_t \leq 2\beta_2 t$ if $B_s \leq 1$ for all $s \in (0, t)$. It is clear that $\mathbb{P}(\max_{s \in (0,t)} B_s > 1)$ goes to 0 as $t \to 0$ so

$$\lim_{t \to 0} \mathbb{P}(X_t / t > 2\beta_2) = 0.$$

This and (4.1) prove the lemma. □

Proof of Theorem 4.1. The assertion of the theorem deals only with probabilities, so we can use any solution to (1.3), as we have uniqueness in law by Theorem 2.1. The same theorem shows that a solution X_t may be constructed so that (X_t, B_t) is a strong Markov process, and hence we may apply excursion theory to it. Recall the discussion at the beginning of Section 3. The same analysis of excursion laws and the exit system applies to the solutions of (1.3) for arbitrary $\alpha_1, \alpha_2 > -1$. Let us briefly recall the facts that we will need in our present argument. Let $D = \{(b, x) \in \mathbb{R}^2 : b = x\}$ and let (H^x, dL) be an exit system for the process of excursions of (B_t, X_t) from the set D. The generic excursion may be denoted (e_t^1, e_t^2). By the translation invariance of the Brownian motion B_t and the equation (1.3), the distribution of $(e_t^1 - x, e_t^2 - x)$ under H^x is the same for every $x \in \mathbb{R}$. Let this distribution be called H_1. Let H_{1+} denote the part of the measure H_1 which is supported on excursions with $e_t^1 > e_t^2$ and let H_{1-} be the part supported on the set where $e_t^1 < e_t^2$. Let H_{2+} be the distribution of $\{e_t^1 - e_t^2, t \in (0, \nu)\}$ under H_{1+} and let H_{2-} have the same definition relative to H_{1-}. We have, up to a multiplicative constant,

$$H_{2+}(A) = \lim_{x \downarrow 0} \frac{1}{|x|} Q_+^x(A), \tag{4.2}$$

where Q_+^x stands for the distribution of the diffusion Y_t with the same infinitesimal variance as Brownian motion (i.e., σ^2) but with drift $-\beta_1 |Y_t|^{\alpha_1}$, killed at the hitting time of 0. We will normalize H_{2+} as in (4.2). We will have to prove that the following formula gives the correct normalization for H_{2-},

$$H_{2-}(A) = \lim_{x \uparrow 0} \frac{1}{|x|} Q_-^x(A). \tag{4.3}$$

Here Q_-^x denotes the distribution of diffusion Z_t with Brownian quadratic variation (namely, σ^2) and drift $-\beta_2 |Z_t|^{\alpha_2}$, killed at the hitting time of 0.

The proof that (4.3) is the correct normalization for H_{2-} can proceed exactly as the proof of Lemma 3.1 (iv), thanks to Lemma 4.2. It only remains to find and compare the formulae analogous to those for $H_{2+}(F_h)$ and $H_{2-}(F_h)$. Recall that F_h is the event that the difference between the maximum and the minimum of an excursion exceeds h. The scale function for a diffusion on $(0, \infty)$ with infinitesimal drift $\mu(x) = -\beta_1 x^{\alpha_1}$ and variance σ^2 is given by (see Karlin and Taylor (1981), p. 194),

$$\begin{aligned} S(x) &= \int_1^x \exp\left(- \int_0^y \frac{2\mu(z)}{\sigma^2} dz \right) dy = \int_1^x \exp\left(- \int_0^y \frac{-2\beta_1 z^{\alpha_1}}{\sigma^2} dz \right) dy \\ &= \int_1^x \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right) dy. \end{aligned} \tag{4.4}$$

By (4.2),

$$\begin{aligned} H_{2+}(F_h) &= \lim_{x \downarrow 0} \frac{1}{x} Q_+^x(T_h < T_0) = \lim_{x \downarrow 0} \frac{1}{x} \cdot \frac{S(x) - S(0)}{S(h) - S(0)} \\ &= \lim_{x \downarrow 0} \frac{1}{x} \cdot \frac{\int_0^x \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right) dy}{\int_0^h \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right) dy} = \frac{1}{\int_0^h \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right) dy}. \end{aligned}$$

If we use (4.3), we obtain in the same way

$$H_{2-}(F_h) = \frac{1}{\int_0^h \exp\left(\frac{-2\beta_2 y^{\alpha_2+1}}{\sigma^2(\alpha_2+1)} \right) dy},$$

which implies that

$$\lim_{h \to 0} H_{2+}(F_h)/H_{2-}(F_h) = 1,$$

and this confirms that the normalization in (4.3) is correct.

The probability for the process Y_t starting from δ never to hit 0 is equal to

$$\lim_{b \to \infty} \frac{S(\delta) - S(0)}{S(b) - S(0)} = \frac{\int_0^\delta \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right) dy}{\int_0^\infty \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right) dy}.$$

It follows that $H_{2+}(F_\infty)$, i.e., the measure given to positive excursions which do not return to 0 is given by

$$\begin{aligned}\lim_{\delta\to 0}\frac{1}{\delta}\cdot\frac{\int_0^\delta \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)}\right)dy}{\int_0^\infty \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)}\right)dy} &= \left[\int_0^\infty \exp\left(\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)}\right)\right]^{-1}\\ = \frac{\left(\frac{-2\beta_1}{\sigma^2(\alpha_1+1)}\right)^{1/(\alpha_1+1)}(\alpha_1+1)}{\Gamma(1/(\alpha_1+1))} &= \frac{(-2\beta_1)^{1/(\alpha_1+1)}(\alpha_1+1)^{\alpha_1/(\alpha_1+1)}}{\sigma^{2/(\alpha_1+1)}\Gamma(1/(\alpha_1+1))} \overset{\mathrm{df}}{=} \lambda_1. \qquad (4.5)\end{aligned}$$

An analogous formula holds for $\lambda_2 \overset{\mathrm{df}}{=} H_{2-}(F_\infty)$. The processes of excursions on both sides are independent so the probability of the negative bifurcation is the same as the probability that the first arrival of an infinite excursion in the Poisson process on the negative side comes before the analogous event on the other side. The probability in question is the ratio of λ_1 and $\lambda_1+\lambda_2$. ☐

Remark 4.3. Mike Harrison pointed out to us that Theorem 4.1 may be proved without using excursion theory. One can calculate the probability that the diffusion $X_t - B_t$ will go to infinity using an explicit formula for the scale function of this diffusion. The excursion theory approach has its advantages, though. First, excursion theory seems to be the right tool for the proof of Theorem 4.4 below. Second, the excursion theory may be used to find the positive bifurcation probability when the vector process (X_t, B_t) is Markov but $X_t - B_t$ is not. The solution of (1.2), studied in Burdzy, Frankel and Pauzner (1998), is an example of such a situation.

Let T_* denote the bifurcation time, i.e., let T_* be the supremum of t with $X_t = B_t$.

Theorem 4.4. *Consider the solution to (1.1) with* $t_0 = x_0 = 0$, $\beta_1 < 0$ *and* $\beta_2 > 0$. *Then*

$$\mathbb{E}T_* = \frac{\sigma^2}{|2\beta_1\beta_2|}.$$

Proof. By Remark 3.2 (ii), the distribution of the excursion law on excursions with finite lifetime remains the same if we change β to $-\beta$. Hence, the formula (3.1) applies in the case $\beta_1 < 0$ and $\beta_2 > 0$, and we have

$$\mathbb{E}V_s = \left(\frac{1}{|\beta_1|}+\frac{1}{|\beta_2|}\right)s,$$

for $V_s = \inf\{t \geq 0 : L_t \geq s\}$. By excursion theory, the infinite excursion of B_t from X_t^0 occurs independently from finite excursions in the Poisson point process of excursions, so the expected bifurcation time is equal to

$$\mathbb{E}T_* = \int_0^\infty \lambda e^{-\lambda s} \mathbb{E}V_s ds,$$

where λ is the intensity of the Poisson process arrival for infinite excursions. We have

$$\lambda = \frac{2(|\beta_1| + |\beta_2|)}{\sigma^2},$$

from (4.5), taking into account infinite excursions on both sides. It follows that

$$\begin{aligned}\mathbb{E}T_* &= \int_0^\infty \lambda e^{-\lambda s} \mathbb{E}V_s ds = \int_0^\infty \lambda e^{-\lambda s} \left(\frac{1}{|\beta_1|} + \frac{1}{|\beta_2|} \right) s ds = \frac{1}{\lambda} \left(\frac{1}{|\beta_1|} + \frac{1}{|\beta_2|} \right) \\ &= \frac{\sigma^2}{2(|\beta_1| + |\beta_2|)} \left(\frac{1}{|\beta_1|} + \frac{1}{|\beta_2|} \right) = \frac{\sigma^2}{|2\beta_1 \beta_2|}. \quad \square\end{aligned}$$

Remark 4.5. (i) It is also the case that

$$\mathbb{E}T_* = \frac{\sigma^2(\beta_1 + \beta_2)}{2\beta_1 \beta_2^2}$$

if $\beta_1, \beta_2 > 0$. We leave the proof to the reader.

(ii) A similar result can be obtained for any values of $\alpha_1, \alpha_2 > -1$ but the formula does not seem to have a compact form, so we only sketch how it can be obtained. The proof of Theorem 4.4 needs two ingredients. One of them is the expected amount of local time before the infinite excursion occurs. This is equal to the expectation of the minimum of two independent exponential random variables whose expected values are inverses of the quantity in (4.5) (for (α_1, β_1) and (α_2, β_2)).

The second ingredient is the expectation of the inverse local time at s, for the process with finite excursions only. This is equal to s times the expected lifetime of a finite excursion under the excursion law. Here is how we can calculate this quantity. For arbitrary $\alpha_1 > -1$ we write as in (4.4),

$$\begin{aligned} s(x) &= \exp\left(-\frac{2\beta_1 x^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right), \\ S(x) &= \int_1^x \exp\left(-\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)} \right) dy. \end{aligned}$$

For $0 < x < y < \infty$, the Green function for Brownian motion Y_t with drift $-\beta_1$ (the negative sign is due to restriction of the excursion law to finite excursions) is given by (see Remark 3.3 on p. 198 of Karlin and Taylor (1981)),

$$G(x,y) = \frac{2[S(x)-S(0)][S(\infty)-S(y)]}{\sigma^2 s(y)[S(\infty)-S(0)]}.$$

Hence, the expected lifetime of an excursion is equal to

$$\begin{aligned}\lim_{x\downarrow 0}\frac{1}{x}\int_0^\infty G(x,y)dy &= \lim_{x\downarrow 0}\frac{1}{x}\int_0^\infty \frac{2[S(x)-S(0)][S(\infty)-S(y)]}{\sigma^2 s(y)[S(\infty)-S(0)]}dy \\ &= \frac{2}{\sigma^2[S(\infty)-S(0)]}\int_0^\infty \frac{[S(\infty)-S(y)]}{s(y)}dy \\ &= \frac{2}{\sigma^2\int_0^\infty \exp\left(-\frac{2\beta_1 z^{\alpha_1+1}}{\sigma^2(\alpha_1+1)}\right)dz}\int_0^\infty \frac{\int_y^\infty \exp\left(-\frac{2\beta_1 z^{\alpha_1+1}}{\sigma^2(\alpha_1+1)}\right)dz}{\exp\left(-\frac{2\beta_1 y^{\alpha_1+1}}{\sigma^2(\alpha_1+1)}\right)}dy.\end{aligned}$$

Adding this to the analogous quantity for α_2 gives the expected lifetime of a finite excursion under the excursion law.

5. Lipschitz approximations. In this section we will address the question of how well a Lipschitz function can approximate a Brownian path. Our analysis will be based on the fact, proved in Lemma 5.2 below, that a certain solution X_t^* to (1.1) may be looked upon as a Lipschitz approximation to B_t.

Our first lemma consists of two elementary observations which are designed to help develop the mental picture of the solutions X_t^x of (1.1), in preparation for Lemma 5.2.

Lemma 5.1 *Let X_t^x denote the solution of (1.1) with $X_0^x = x$.*
(i) If $x < y$ then $X_t^x < X_t^y$ for all $t \in \mathbb{R}$, a.s.
(ii) For a fixed t, the function $x \to X_t^x$ is continuous a.s.

Proof. (i) Suppose that we have $x < y$ and $X_s^x = X_s^y$ for some $s \in \mathbb{R}$. The two functions X_t^x and X_t^y are not identical since $X_0^x = x \neq y = X_0^y$, but they are both solutions to (1.1) with $t_0 = s$ and $x_0 = X_s^x$. This contradicts the uniqueness of solutions to (1.1).

(ii) Consider any sequence x_n converging monotonically to $x_\infty \in \mathbb{R}$. By (i), the sequence $X_t^{x_n}$ is also monotone in n, and by the Lipschitz property it must converge to a limit X_t^∞. The Lipschitz property of the $X_t^{x_n}$'s implies that of X_t^∞. We can show that X_t^∞ is a solution to (1.1) using the same argument as in the proof of existence in Theorem 2.2 for (1.1). We must have $X_0^\infty = X_0^{x_\infty}$, so the uniqueness of the solutions to (1.1) implies that $X_t^\infty = X_t^{x_\infty}$ for all t, a.s. We have shown that $x_n \to x_\infty$ implies $X_t^{x_n} \to X_t^{x_\infty}$. This completes the proof. $\square$

Lemma 5.2. *Assume that* $\beta_1 < 0 < \beta_2$. *For almost every* ω *there exists a unique* $\overline{x} = \overline{x}(\omega)$ *such that the solution* $X_0^{\overline{x}}$ *to (1.1), that is, the solution satisfying* $X_0^{\overline{x}}(\omega) = \overline{x}(\omega)$, *has the property that there exist arbitrarily large* t *with* $X_t^{\overline{x}}(\omega) = B_t(\omega)$.

It is easy to see that if $\beta_1 < 0 < \beta_2$ then with probability 1, all solutions X_t^x have the property that there exist arbitrarily small $t > -\infty$ such that $X_t^x = B_t$. Lemma 2.13 shows that a result analogous to Lemma 5.2 holds when $\beta_2 < 0 < \beta_1$, and we require that the solution intersects the Brownian path for arbitrarily small $t > -\infty$.

Proof. We will first prove the existence. The law of the iterated logarithm easily implies that for some random $x > 0$, the functions $t \to x + \beta_2 t$ and $t \to -x + \beta_1 t$ stay above and below the trajectory of B_t, for $t \geq 0$, resp. This shows that there exist both large and small (random) x such that X_t^x does not intersect the trajectory of B_t for $t > 0$.

Let A be the set of all x such that $X_t^x > B_t$ for all t greater than some $t_1 = t_1(x)$. By Lemma 5.1 (i) and the above remarks, the set A is a non-empty semi-infinite interval. We will show that it is open. Consider an x such that $X_t^x > B_t$ for all t greater than some t_1. Then $X_t^x = X_{t_1}^x + \beta_2(t - t_1)$ for $t > t_1$. Let $c_1 = \inf\{X_t^x - B_t : t > t_1 + 1\}$ and note that $c_1 > 0$, by the continuity of $X_t^x - B_t$. By Lemma 5.1 (ii), the function $y \to X_{t_1+1}^y$ is continuous so we can find $\varepsilon > 0$ such that $X_{t_1+1}^y > X_{t_1+1}^x - c_1/2$ for all $y > x - \varepsilon$. It follows easily that for such y, we have $X_t^y = X_{t_1+1}^x + \beta_2(t - t_1 - 1)$ and so $X_t^y > B_t$ for $t > t_1 + 1$. This proves that A is open. The same is true of the set A' of x's with the property that $X_t^x < B_t$ for all t greater than some $t_1 = t_1(x)$. Hence, $(A \cup A')^c$ is non-empty and so we must have at least one x for which $X_t^x = B_t$ for arbitrarily large t.

We turn to the proof of uniqueness. Suppose that with positive probability there exist $x_1 < x_2$, such that both trajectories $X_t^{x_1}$ and $X_t^{x_2}$ intersect B_t for arbitrarily large times t. Then we can find $\delta > 0$ and $p > 0$ such that with probability greater than p, there exist x_1 and x_2 with $x_2 > x_1 + \delta$ and such that $X_t^{x_1}$ and $X_t^{x_2}$ intersect B_t for arbitrarily large times t. We will show that this assumption leads to a contradiction.

Fix some $\gamma \in (1/2, 1)$. By the law of the iterated logarithm, we can find a large t_1 with the following property. For every x, if $|X_{t_1}^x| \geq t_1^\gamma$ then $X_t^1 \neq B_t$ for all $t > t_1$, with probability greater than $1 - p/8$,.

Consider solutions $\widehat{X}_t^{y_1}$ and $\widehat{X}_t^{y_2}$ to (1.1) with $\widehat{X}_{t_1}^{y_1} = y_1 \overset{\text{df}}{=} t_1^\gamma$ and $\widehat{X}_{t_1}^{y_2} = y_2 \overset{\text{df}}{=} -t_1^\gamma$. We enlarge t_1, if necessary, so that the event $\{|B_{t_1/2}| \geq t_1^\gamma\} \cup \{|B_{t_1}| \geq t_1^\gamma\}$ has a probability smaller than $p/8$. If the event $\{|B_{t_1/2}| \geq t_1^\gamma\} \cup \{|B_{t_1}| \geq t_1^\gamma\}$ does not occur and t_1 is sufficiently large, then both processes $\widehat{X}_t^{y_1}$ and $\widehat{X}_t^{y_2}$ must intersect the trajectory of $\widetilde{B}_t$ between $t_1/2$ and t_1. Let $T = \sup\{t < t_1 : \widehat{X}_t^{y_1} = B_t\}$. Then the process $\{Y_t = B_{T-t} - \widehat{X}_{T-t}^{y_1}, t \geq 0\}$ is a Brownian motion with drift β_2 if $Y_t < 0$ and β_1 if $Y_t > 0$. Note that the distribution of the process Y_t does not depend on t_1. We can apply Proposition 3.3 to the local time L_t^Y of Y_t at 0, to see that $L_t^Y/t \to (1/|\beta_1| + 1/|\beta_2|)^{-1} \overset{\text{df}}{=} \lambda$, as $t \to \infty$, a.s. Enlarge t_1 again, if needed, so that $L_{t_1/2}^Y > \lambda t_1/4$ with probability exceeding $1 - p/8$. Let η be the expected number of positive excursions of Y whose height does not exceed δ, whose duration exceeds 1, and which start at a time t with $L_t^Y \leq 1$. Then the total number of such excursions which start at times t with $L_t^Y < \lambda t_1/4$ has a Poisson distribution with mean $\eta\lambda t_1/4$. We make t_1 large enough so that with probability greater than $1 - p/8$, the total number of such excursions which start at times t with $L_t^Y < \lambda t_1/4$, is greater than $\eta\lambda t_1/8$. Collecting the above facts, we see that with probability greater than $1 - 3p/8$, we have all of the following: (i) $T \in (t_1/2, t_1)$, (ii) the local time for the process $\widehat{X}_t^{y_1} - B_t$ at 0 accumulated between times 0 and t_1 exceeds $\lambda t_1/4$, and (iii) the number of negative excursions of $\widehat{X}_t^{y_1} - B_t$ whose absolute height is less than δ, the duration is greater than 1, and which lie within interval $(0, t_1)$, is greater than $\eta\lambda t_1/8$. Note that $dX_t^{y_2}/dt - dX_t^{y_1}/dt = \beta_2 - \beta_1$ for any t within such an excursion provided $\widehat{X}_t^{y_1} > \widehat{X}_t^{y_2} + \delta$. The last observation shows that if $\widehat{X}_0^{y_1} > \widehat{X}_0^{y_2} + \delta$ then $\widehat{X}_{t_1}^{y_1} > \widehat{X}_{t_1}^{y_2} + \delta + 2(\beta_2 - \beta_1)\eta\lambda t_1/8$. If t_1 is sufficiently large the last inequality cannot hold because we would have $t_1^\gamma > -t_1^\gamma + \delta + 2(\beta_2 - \beta_1)\eta\lambda t_1/8$. We conclude that with probability greater than $1 - 3p/8$, we have $\widehat{X}_0^{y_1} - \widehat{X}_0^{y_2} < \delta$.

We reformulate the last statement in terms of x_1 and x_2. Using Lemma 5.1 (i), we see that the probability that there exist x_1 and x_2 with $x_2 > x_1 + \delta$, $|X_{t_1}^{x_1}| \leq t_1^\gamma$ and $|X_{t_1}^{x_2}| \leq t_1^\gamma$ is less than $3p/8$. An earlier argument showed that the probability that $x_2 > x_1 + \delta$ and $|X_{t_1}^{x_1}| \geq t_1^\gamma$ or $|X_{t_1}^{x_2}| \geq t_1^\gamma$ is less than $2p/8$. We conclude that the probability of $x_2 > x_1 + \delta$ is bounded by $5p/8$, which contradicts our assumption. $\square$

Consider equation (1.1) with $-\beta_1 = \beta_2 = \beta > 0$. Let X_t^* denote the solution of (1.1) constructed in Lemma 5.2. That is, $X_t^* = X_t^{\overline{x}}$.

Lemma 5.3. *We have with probability 1,*

$$\limsup_{t\to-\infty} \frac{X_t^* - B_t}{\log t} = \limsup_{t\to\infty} \frac{X_t^* - B_t}{\log t} = \limsup_{t\to-\infty} \frac{B_t - X_t^*}{\log t} = \limsup_{t\to\infty} \frac{B_t - X_t^*}{\log t} \geq \frac{\sigma^2}{2\beta}.$$

Note the lim inf's as $t \to \infty$ are zero as X_t^* crosses B_t for arbitrarily large t.

Proof. Let $\widetilde{X}_t$ be a solution to (1.1) with $-\beta_1 = \beta_2 = -\beta$ and let $Y_t = \widetilde{B}_t - \widetilde{X}_t$. The process Y_t is a diffusion which spends zero time on the real axis, which behaves like Brownian motion with drift β when $Y_t < 0$, and it is a Brownian motion with drift $-\beta$ when $Y_t > 0$. By Karlin and Taylor (1981), Chapter 15.5, (5.34), the process Y_t has a stationary probability distribution with a density

$$\psi(y) = \frac{\beta}{\sigma^2} \exp\left(-\frac{2\beta|y|}{\sigma^2}\right).$$

Let $\{\widehat{Y}_t, t \in \mathbb{R}\}$ be the process which has density $\psi(y)$ for every fixed t, and which has the transition probabilities of Y_t. Let

$$\widehat{X}_t = \int_0^t \operatorname{sgn}(\widehat{Y}_s)\beta ds$$

and

$$\widehat{B}_t = \widehat{Y}_t - \widehat{Y}_0 + \widehat{X}_t.$$

It is easy to check that $\widehat{B}_t$ is a Brownian motion with $\widehat{B}_0 = 0$, and that $\widehat{X}_t$ solves (1.1) with $\widetilde{B}_t$ replaced by $\widehat{B}_t$ and $\beta_1 = -\beta_2 = \beta$. Moreover, $\widehat{X}_t$ has the property that $\widehat{X}_t = \widehat{B}_t$ for infinitely many arbitrarily large negative and arbitrarily large positive t. If we now time-reverse $\widehat{B}_t$ and $\widehat{X}_t$, we will obtain a Brownian motion and a corresponding solution to (1.1) which satisfies the defining properties of X_t^*. Hence, we may construct B_t and the corresponding process X_t^* by letting $B_t = \widehat{B}_{-t}$ and $X_t^* = \widehat{X}_{-t}$.

The scale function $S(y)$ for Brownian motion with drift $-\beta$ is given by $S(y) = \exp(2\beta y/\sigma^2)$ (Karlin and Taylor (1981) Chapter 15.4). Let T_a be the hitting time of a by the process Y. The mass $H(F_h)$ given by the excursion law for the process $\widehat{Y}_t$ to positive excursions whose height exceeds h is equal to

$$\begin{aligned}\lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \mathbb{P}^{\varepsilon}(T_h < T_0) &= \lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \cdot \frac{S(\varepsilon) - S(0)}{S(h) - S(0)} = \lim_{\varepsilon \downarrow 0} \frac{1}{\varepsilon} \cdot \frac{\exp(2\beta\varepsilon/\sigma^2) - 1}{\exp(2\beta h/\sigma^2) - 1} \\ &= \frac{2\beta}{\sigma^2} \cdot \frac{1}{\exp(2\beta h/\sigma^2) - 1}.\end{aligned}$$

Fix some small $\varepsilon > 0$ and let $h_k = k \log 2 \cdot (1 - \varepsilon)\sigma^2/(2\beta)$. Let L_t denote the local time of $\widehat{Y}_t$ at 0 with $L_0 = 0$, and let A_k denote the event that there exists a positive excursion of $\widehat{Y}_t$ whose height exceeds h_k, and which starts at a time t such that $2^k \le L_t < 2^{k+1}$. The probability of A_k is the probability that a Poisson random variable with mean $\lambda_k = 2^k H(F_{h_k})$ takes a non-zero value. Thus, $\mathbb{P}(A_k^c) = e^{-\lambda_k}$. For large k,

$$\begin{aligned}\lambda_k &= 2^k \cdot \frac{2\beta}{\sigma^2} \cdot \frac{1}{\exp(2\beta h_k/\sigma^2) - 1} \ge 2^k \cdot \frac{2\beta}{\sigma^2} \exp(-2\beta h_k/\sigma^2) \\ &= 2^k \cdot \frac{2\beta}{\sigma^2} \exp\left(-2\frac{\beta}{\sigma^2} \cdot \frac{k \log 2 \cdot (1-\varepsilon)\sigma^2}{2\beta}\right) = 2^k \cdot \frac{2\beta}{\sigma^2} \cdot 2^{-k(1-\varepsilon)} = \frac{2\beta}{\sigma^2} \cdot 2^{k\varepsilon}.\end{aligned}$$

This implies that $\sum_k \mathbb{P}(A_k^c) = \sum_k e^{-\lambda_k} < \infty$. By the Borel-Cantelli Lemma, only a finite number of the events A_k^c occur. Hence,

$$\begin{aligned}\limsup_{t\to\infty} \frac{\widehat{Y}_t}{\log L_t} &\ge \limsup_{k\to\infty} \ \sup\left\{\frac{\widehat{Y}_t}{\log L_t} : L_t \in [2^k, 2^{k+1}]\right\} \\ &\ge \limsup_{k\to\infty} \ \sup\left\{\frac{\widehat{Y}_t}{\log 2^{k+1}} : L_t \in [2^k, 2^{k+1}]\right\} \\ &\ge \limsup_{k\to\infty} \frac{h_k}{(k+1)\log 2} \\ &= \limsup_{k\to\infty} \frac{k \log 2 \cdot (1-\varepsilon)\sigma^2}{2\beta(k+1)\log 2} \\ &= \frac{(1-\varepsilon)\sigma^2}{2\beta}.\end{aligned}$$

Since $\varepsilon > 0$ is arbitrarily small and, by Proposition 3.3, $\lim_{t\to\infty} L_t/t = \beta/2$, a.s., we obtain, with probability 1,

$$\limsup_{t\to\infty} \frac{\widehat{Y}_t}{\log t} = \frac{\sigma^2}{2\beta}.$$

A similar argument yields,

$$-\liminf_{t\to\infty} \frac{\widehat{Y}_t}{\log t} = \limsup_{t\to-\infty} \frac{\widehat{Y}_t}{\log t} = -\liminf_{t\to\infty} \frac{\widehat{Y}_t}{\log t} = \frac{\sigma^2}{2\beta}.$$

Recall from the first part of the proof that $\widehat{Y}_t = B_{-t} - X^*_{-t} - \widehat{Y}_0$. This combined with the results for $\widehat{Y}_t$ implies the proposition. □

The function $t \to a + \beta|t|$ is Lipschitz with constant β. For some random a, this function is greater than B_t for every t, by the law of the iterated logarithm. Since the infimum of an arbitrary family of Lipschitz functions with constant β is again a Lipschitz function with constant β, there exists a smallest Lipschitz function Z_t^+ with constant β with the property that $Z_t^+ \geq B_t$ for all t. Let Z_t^- be the largest Lipschitz function with constant β such that $Z_t^- \leq B_t$ for all t. Note that Z_t^+ and Z_t^- are not measurable with respect to $\sigma\{B_s, s \leq t\}$.

Lemma 5.4. *Assume that $B_0 = 0$. We have with probability 1,*

$$\limsup_{t\to-\infty} \frac{Z_t^+ - Z_t^-}{\log t} = \limsup_{t\to\infty} \frac{Z_t^+ - Z_t^-}{\log t} \leq \frac{\sigma^2}{2\beta}.$$

Proof. Consider $a_1, a_2 > 0$. Let

$$A_{++} = \{\exists t > 0 : B_t = a_1 + \beta t\}, \qquad A_{+-} = \{\exists t > 0 : B_t = -a_2 - \beta t\},$$
$$A_{-+} = \{\exists t < 0 : B_t = a_1 - \beta t\}, \qquad A_{--} = \{\exists t < 0 : B_t = -a_2 + \beta t\}.$$

The probability that B_t ever hits the line $t \to a_1+\beta t$ is equal to $\exp(-2a_1\beta/\sigma^2)$ (Karlin and Taylor (1975), p. 362). The probability that B_t crosses the line $a_1 + \beta t$ at some $t_1 > 0$ and then crosses the line $-a_2-\beta t$ for some $t > t_1$ is bounded by $\exp(-2a_1\beta/\sigma^2)\exp(-2a_2\beta/\sigma^2)$, by the strong Markov property applied at t_1. The probability of crossing first $-a_2 - \beta t$ and then $a_1 + \beta t$ is bounded by the same quantity. Hence,

$$\mathbb{P}(A_{++} \cap A_{+-}) \leq 2\exp(-2(a_1 + a_2)\beta/\sigma^2).$$

The same estimate holds for $\mathbb{P}(A_{--} \cap A_{-+})$, by symmetry. We obtain

$$\mathbb{P}(A_{++} \cap A_{--}) = \mathbb{P}(A_{-+} \cap A_{+-}) = \exp(-2(a_1 + a_2)\beta/\sigma^2),$$

from the independence of the processes $\{B_t, t \geq 0\}$ and $\{B_t, t \leq 0\}$. It follows that

$$\begin{aligned}
&\mathbb{P}(Z_0^+ - B_0 \geq a_1, B_0 - Z_0^- \geq a_2) = \mathbb{P}(Z_0^+ \geq a_1, Z_0^- \leq -a_2) \\
&\quad \leq \mathbb{P}([A_{++} \cap A_{+-}] \cup [A_{--} \cap A_{-+}] \cup [A_{++} \cap A_{--}] \cup [A_{-+} \cap A_{+-}]) \\
&\quad \leq 8\exp(-2(a_1 + a_2)\beta/\sigma^2).
\end{aligned}$$

Choose $\varepsilon \in (0, 1)$. Let $m > 8$ be an integer large enough that $(m-1)/(m(1-\varepsilon)) > 1$. We have for any $y > 0$,

$$\begin{aligned}
\mathbb{P}(Z_0^+ - Z_0^- \geq y) &\leq \sum_{j=0}^{m} \mathbb{P}(Z_0^+ - B_0 \geq jy/m, B_0 - Z_0^- \geq (m - j - 1)y/m) \\
&\leq \sum_{j=0}^{m} 8\exp\left(-2\left(\frac{jy}{m} + \frac{(m-j-1)y}{m}\right)\frac{\beta}{\sigma^2}\right) \\
&\leq 9m\exp\left(\frac{-2(m-1)y\beta}{m\sigma^2}\right).
\end{aligned}$$

Fix some large $b < \infty$. Consider an integer $k > 0$. Let n be the integer part of

$$\frac{2\beta(1-\varepsilon)b2^k}{\sigma^2 k \log 2},$$

and let $x_k = b2^k/n$, and $t_j^k = j2^k/n$. We have,

$$\begin{aligned}
\mathbb{P}(Z^+_{t_j^k} - Z^-_{t_j^k} \geq x_k) &= \mathbb{P}(Z^+_0 - Z^-_0 \geq x_k) \\
&\leq 9m \exp\left(\frac{-2(m-1)x_k\beta}{m\sigma^2}\right) \\
&= 9m \exp\left(-\frac{(m-1)2\beta b 2^k}{mn\sigma^2}\right) \\
&\leq 9m \exp\left(-\frac{(m-1)2\beta b 2^k \sigma^2 k \log 2}{m 2\beta(1-\varepsilon)b2^k\sigma^2}\right) \\
&= 9m \exp\left(\frac{-k(m-1)\log 2}{m(1-\varepsilon)}\right) = 9m \cdot 2^{-k(m-1)/(m(1-\varepsilon))}.
\end{aligned}$$

For some $c_1 < \infty$, using $(m-1)/(m(1-\varepsilon)) > 1$, we obtain,

$$\begin{aligned}
\sum_{k=1}^{\infty} \sum_{0 \leq t_j^k \leq 2^k} \mathbb{P}(Z^+_{t_j^k} - Z^-_{t_j^k} \geq x_k) &\leq c_1 \sum_{k=1}^{\infty} 2n \cdot 9m \cdot 2^{-k(m-1)/(m(1-\varepsilon))} \\
&\leq c_1 \sum_{k=1}^{\infty} \frac{2\beta(1-\varepsilon)b2^k}{\sigma^2 k \log 2} \cdot 36m \cdot 2^{-k(m-1)/(m(1-\varepsilon))} < \infty.
\end{aligned}$$

By the Borel-Cantelli lemma, for all sufficiently large k and all $t_j^k \in [0, 2^k]$, we have $Z^+_{t_j^k} - Z^-_{t_j^k} \leq x_k$. If $Z^+_{t_j^k} - Z^-_{t_j^k} \leq x_k$ then for $t \in [(t_j^k + t_{j-1}^k)/2, (t_j^k + t_{j+1}^k)/2]$,

$$Z^+_t - Z^-_t \leq x_k + 2\beta|t - t_j| \leq b2^k/n + \beta 2^k/n = (b2^k/n)(1 + \beta/b) = x_k(1 + \beta/b).$$

This implies that for large k, we have for all $t \in [0, 2^k]$,

$$Z^+_t - Z^-_t \leq x_k(1 + \beta/b).$$

We obtain

$$\begin{aligned}
\limsup_{t\to\infty} \frac{Z_t^+ - Z_t^-}{\log t} &\le \limsup_{k\to\infty} \sup_{t\in[2^{k-1},2^k]} \frac{Z_t^+ - Z_t^-}{\log t} \\
&\le \limsup_{k\to\infty} \sup_{t\in[2^{k-1},2^k]} \frac{Z_t^+ - Z_t^-}{\log 2^{k-1}} \\
&\le \limsup_{k\to\infty} \frac{x_k(1+\beta/b)}{(k-1)\log 2} \\
&\le \limsup_{k\to\infty} \frac{(b2^k/n)(1+\beta/b)}{(k-1)\log 2} \\
&\le \limsup_{k\to\infty} \frac{b2^k\sigma^2 k \log 2(1+\beta/b)}{2\beta(1-\varepsilon)b2^k(k-1)\log 2} \\
&= \frac{\sigma^2(1+\beta/b)}{2\beta(1-\varepsilon)}.
\end{aligned}$$

Since ε may be chosen arbitrarily small and b may be chosen arbitrarily large, with probability 1,

$$\limsup_{t\to\infty} \frac{Z_t^+ - Z_t^-}{\log t} \le \frac{\sigma^2}{2\beta}.$$

The result for $t \to -\infty$ follows by symmetry. □

Theorem 5.5. *(i) With probability 1,*

$$\begin{aligned}
\limsup_{t\to-\infty} \frac{X_t^* - B_t}{\log t} &= \limsup_{t\to\infty} \frac{X_t^* - B_t}{\log t} \\
&= \limsup_{t\to-\infty} \frac{B_t - X_t^*}{\log t} = \limsup_{t\to\infty} \frac{B_t - X_t^*}{\log t} \\
&= \limsup_{t\to-\infty} \frac{Z_t^+ - Z_t^-}{\log t} = \limsup_{t\to\infty} \frac{Z_t^+ - Z_t^-}{\log t} = \frac{\sigma^2}{2\beta}.
\end{aligned}$$

(ii) $\mathbb{E}|B_t - X_t^*| = \frac{1}{2}\cdot\sigma^2/\beta$, *for every* $t \in \mathbb{R}$.
(iii) $\mathbb{E}(Z_t^+ - B_t) = \mathbb{E}(B_t - Z_t^-) = \frac{3}{4}\cdot\sigma^2/\beta$, *for every* $t \in \mathbb{R}$.

Theorem 5.5 (i) shows, in a sense, that Z^+ and Z^- are as good Lipschitz approximations to B_t as X^*. However, the comparison comes out differently when we look at the averages presented in (ii) and (iii).

Proof. It is elementary to check that we always have $Z_t^- \le X_t^* \le Z_t^+$. This and Lemmas 5.3 and 5.4 yield (i).

Recall the stationary density $\psi(y)$ for Y_t from the proof of Lemma 5.3. This is the same as the density for the distribution of $B_t - X_t^*$. Hence

$$\mathbb{E}|B_t - X_t^*| = \int_{-\infty}^{\infty} |y| \frac{\beta}{\sigma^2} \exp\left(-\frac{2\beta|y|}{\sigma^2}\right) dy = \frac{1}{2} \cdot \frac{\sigma^2}{\beta},$$

which proves (ii).

For $a > 0$, the probability that B_t crosses the line $a + \beta t$ for some $t > 0$ is equal to $\exp(-2a\beta/\sigma^2)$ (Karlin and Taylor (1975) p. 362). This is the same as the probability of crossing the line $a - \beta t$ for some $t < 0$. The probability that none of these events happen is $[1 - \exp(-2a\beta/\sigma^2)]^2$, and so

$$\mathbb{P}(Z_0^+ < a) = [1 - \exp(-2a\beta/\sigma^2)]^2.$$

This yields

$$\mathbb{E}Z_0^+ = \frac{3\sigma^2}{4\beta}.$$

We similarly have $\mathbb{E}Z_0^- = -3\sigma^2/(4\beta)$, and by translation invariance, for every t,

$$\mathbb{E}(Z_t^+ - B_t) = \mathbb{E}(B_t - Z_t^-) = \frac{3\sigma^2}{4\beta}. \quad \square$$

If we let $\alpha_1 = \alpha_2 = 1$ and choose suitable β_1 and β_2 in (1.3), then $Y_t = X_t - B_t$ is an Ornstein-Uhlenbeck process. Results for such a process, closely related to Theorem 5.5 (i), can be found in the paper of Darling and Erdös (1956).

Corollary 5.6. *For any random Lipschitz function $g(t)$ with constant β we have with probability one*

$$\limsup_{t\to\infty} \frac{g(t) - B_t}{\log t} \geq \sigma^2/(4\beta).$$

Proof. Suppose that $X_t^* - B_t = a$ for some t and $a > 0$. Let s be the largest time less than t such that $B_s = X_s^*$. Then we see that the quantity $\sup_{s\leq u\leq t} |g(u) - B_u|$ cannot be smaller than $a/2$ for any Lipschitz function $g(u)$ with constant β, by comparing $g(u)$ with the function $u \to B_s + a/2 + (u - s)\beta$. Since $\limsup_{t\to\infty} (X_t^* - B_t)/\log t = \sigma^2/(2\beta)$, for any Lipschitz function $g(t)$ with constant β we must have

$$\limsup_{t\to\infty} \frac{g(t) - B_t}{\log t} \geq \sigma^2/(4\beta). \quad \square$$

Corollary 5.6 sheds some new light on an old problem about strong approximations. Let us assume that $\sigma^2 = 1$, i.e., we will consider now only standard Brownian motion. Suppose that $\{V_k\}_{k\geq 1}$ are i.i.d. random variables such that $|V_k| \leq \beta$, a.s. Let $S_n = \sum_{k=1}^n V_k$ and extend the function $n \to S_n$ to all positive real values by linear interpolation between S_n and S_{n+1}. Note that the random function S_t is Lipschitz with constant β.

The following is an immediate consequence of Corollary 5.6.

Theorem 5.7. *Suppose that V_k and S_t are as above. If S_t and B_t are constructed on the same probability space (but not necessarily independent), then*

$$\limsup_{t\to\infty} \frac{S_t - B_t}{\log t} \geq 1/(4\beta). \tag{5.1}$$

Theorem 2.3.2 of Csörgö and Révész (1981) says that if the V_k have finite variance and

$$\limsup_{t\to\infty} \frac{|S_t - B_t|}{\log t} = 0,$$

then the V_k have a standard normal distribution. Our result (5.1) may be interpreted as a quantitative version of the same theorem, in the case when $|V_k|$ are bounded. A remarkable theorem of Komlós, Major and Tusnády (see Csörgö and Révész (1981) Theorem 2.6.1) implies that if the V_k are bounded, then one may construct S_t and B_t on a common probability space so that

$$\limsup_{t\to\infty} \frac{|S_t - B_t|}{\log t} \leq C < \infty. \tag{5.2}$$

It is striking that one can achieve the same logarithmic order of approximation for a Lipschitz function S_t with independent increments $S_n - S_{n-1}$, as for an arbitrary Lipschitz function $g(t)$ with constant β. Rio (1991) proved that (5.2) holds with $C = 9/2$ if V_k are centered Poisson variables (the estimate had appeared in Section 5 of the preprint; that section was not included in the final version of the article, Rio (1994)). No other estimates for C seem to be known so (5.1) is our own modest contribution to the field of strong approximations.

6. Open problems.

We list a few questions we were not able to answer in this paper.

(i) Can one prove pathwise uniqueness in Theorem 2.1 if one or both α_1 and α_2 belong to $(-1, 0)$?

(ii) Does a result analogous to Theorem 3.7 hold for $\beta_1, \beta_2 > 0$ with $\beta_1 - \beta_2 < 0$? A similar question can be asked about the case when $\beta_1 < 0 < \beta_2$; in the last case a special solution to (1.1), defined in Lemma 5.2, would have to play an important role. Can one generalize Theorem 3.7 to local times corresponding to solutions of (1.3) with α_1 and α_2 not necessarily equal to 0?

(iii) Find the best $\gamma = \gamma(\alpha_1, \alpha_2, \beta_1, \beta_2) > 0$ in Lemma 4.2.

(iv) Find the best constants in (5.1) and (5.2).

(v) Does there exist a unique Lipschitz solution to (2.3) if B_t is a fractional Brownian motion of index $H \in (1/2, 1)$?
